A QUANTITATIVE COMPARISON OF CASEIN, LACTALBUMIN, AND EDESTIN FOR GROWTH OR MAINTENANCE.*

BY THOMAS B. OSBORNE AND LAFAYETTE B. MENDEL.

WITH THE COOPERATION OF EDNA L. FERRY AND ALFRED J. WAKEMAN.

(From the Laboratory of the Connecticut Agricultural Experiment Station
and the Sheffield Laboratory of Physiological Chemistry
in Yale University, New Haven.)

(Received for publication, June 3, 1916.)

Our earliest attempts¹ to make quantitative comparisons of the nutritive values of different proteins for either growth or maintenance were subject to the criticism that the food intake was not sufficiently controlled to justify positive conclusions unless the nutritive differences between the proteins under investigation were very pronounced. The data furnished by the former trials in which the size of the animal and the food intakes were fairly comparable indicated, however, that not only were these proteins unlike in their efficiency when used in the same proportion as supplements to an inadequate protein like zein,² but the rate of growth on foods containing the same percentages of these proteins was quite unlike. As food was offered *ad libitum* to the animals it rarely happened that the total caloric intake, the absolute amount of protein eaten, the quantities of inorganic salts, or amount of "food accessories," were strictly comparable.

We have endeavored therefore to plan our latest experiments so as to meet all criticisms of this sort. When animals grow they require more nutriment, owing to the increased amount of tissue formed. Obviously the efficiency of a diet for an animal which grows cannot be compared quantitatively with that of a diet upon which an animal makes little, if any, growth. The

* The expenses of this investigation were shared by the Connecticut Agricultural Experiment Station and the Carnegie Institution of Washington, D. C.

¹ Osborne, T. B., and Mendel, L. B., *J. Biol. Chem.*, 1915, xx, 351; 1915, xxii, 241.

² Osborne and Mendel, *J. Biol. Chem.*, 1914, xvii, 325.

question may fairly be asked: Does the one animal grow because it eats more or the other fail to grow because it eats less? Definite conclusions can only be drawn from experiments where, during the same period of time, substantially the same amount of food was eaten by animals of corresponding size. Such conditions can be established only by feeding weighed quantities of food in amounts so chosen that the animal will consume all that is offered each day.

In order to learn the minimal amount of food needed for a normal rate of growth several young rats were fed on weighed quantities of a ration of the isolated food materials which, in our earliest experiments, we had fed *ad libitum*. By increasing or decreasing, from day to day, the quantity of food offered, according as the weight of the animal fell below or above the normal, the growth was so controlled as to keep all of the animals growing at very nearly the same rate. Little difficulty was encountered in inducing the animals to eat all of the food offered, since the amount supplied was somewhat below that ordinarily consumed by them when fed *ad libitum*. On the following diet:

	per cent
Lactalbumin.....	18
"Protein-free milk".....	28
Starch.....	28
Butter fat.....	18
Lard.....	8

the weekly intake in the case of the two males, started at essentially the same age and size, thus limited daily in quantity, was as follows:

Normal Growth, Limited Daily Feeding.

Week of limited feeding.	Rat 2586.		Rat 2593.		Average food intake per week.
	Food intake per week.	Gain in body weight.	Food intake per week.	Gain in body weight.	
	gm.	gm.	gm.	gm.	
1	22.9	8	25.5	9	24.2
2	39.0	20	40.0	20	39.5
3	39.5	15	44.5	12	42.0
4	48.0	17	45.0	16	46.5
5	49.5	9	51.0	15	50.3
Total	198.9	69	206.0	72	202.5

Inasmuch as excess of protein fed does not increase the rate of growth beyond the normal limits "constitutionally fixed" for the individual it seemed desirable, in instituting any careful comparison of the physiological value of different proteins, to avoid, if possible, feeding even the slightest excess above the minimum actually required for so called normal growth. It was therefore planned to imitate the preliminary experiments just referred to—which were carried out with a protein, lactalbumin, that had already given some justification for the belief in its superior nutrient value—by trials with limited daily food intakes precisely alike in energy content, inorganic and accessory food ingredients, etc., for each day, in Series A.

Series A.—This series was to be varied in respect to the protein added. The food intake was uniformly about 10 per cent lower than that in the preliminary series, so that in any event there would be no unnecessary surplus of food ingested. The rats—all males—were of approximately the same body weight (45 to 50 gm.) at the beginning of the experiment. With conditions thus favorably selected, so that the diet would barely suffice for growth at a normal rate when the protein employed was as efficient as the lactalbumin which had served as the guide for the quantities needed, further trials were begun with edestin and with casein, alone or with the addition of the amino-acids cystine or alanine. The period of comparison in this series lasted 77 days. The animals, almost without exception, consumed all of the food offered to them daily, so that the total intake for the entire period in each of the large number of experiments undertaken scarcely varied more than 2 or 3 gm. Whenever an animal showed any abnormality, such as a continued failure to eat, it was discarded; and accordingly no data from such aberrant individuals are included in the statistical averages which are tabulated in Table I. This shows the initial weights of the rats, the food intakes in the successive weeks of the entire period, and the total gains made in body weight up to the end of each successive week. In view of the fairly comparable character of the results obtained with different individuals in the same series of the trials, it has seemed justifiable to compare weekly averages for each group. These are summarized in Table II. The composition of the foods was as follows:

	<i>per cent</i>
Protein.....	8.0-20.45
"Protein-free milk".....	28
Starch }	36-23
Sucrose }	
Butter fat.....	18
Lard.....	7-12

When amino-acids were fed with casein they represented an addition equivalent to 3 per cent of the added protein.

An inspection of these statistics will show that in animals of the same sex, with the same initial body weight, and the same total food intake furnished daily in precisely equivalent and increasing amounts in successive periods of the experiment, in accord with the anticipated needs of increasing body weight, *the lactalbumin foods in every case produced the largest gains.* For example, the average total gain in 11 weeks upon the diet containing 14.8 per cent of lactalbumin was 122 gm., in contrast with the gain of 105 gm. and 95 gm. on similar diets of 16.2 per cent of casein and 16.7 per cent of edestin respectively. Even with larger percentages of these proteins (casein 19.8 per cent and edestin 20.5 per cent) the total gains are below that obtained on a smaller daily intake of protein in the form of lactalbumin. The highest concentrations of other proteins here recorded likewise have failed to exceed to any significant extent the average total gain with lactalbumin foods containing only 9.9 per cent of this protein.

In view of the fact that the food intakes were strictly comparable in these experiments, and that the trials were extended over a very long period during which temporary remissions or accelerations of growth might easily correct themselves, *the superior efficiency of lactalbumin in the nutrition of growth is demonstrated beyond question.* Incidentally it should be noted that inasmuch as the animals were all receiving the same absolute amounts of food on the corresponding day of each period, the rapidly growing animals were actually put at a *disadvantage* in having a smaller allowance of food *per unit of body weight* as the result of the superior growth-promoting qualities of the protein ingested.

We have intimated elsewhere³ that the comparative inferiority of casein foods in producing growth when smaller amounts, *e.g.*,

³ Osborne and Mendel, *J. Biol. Chem.*, 1915, xx, 351.

9 per cent, of the protein are furnished in the ration, can be corrected by the addition of the essential amino-acid cystine which this protein yields in relatively small amounts as compared with most other proteins. Our newer experiments in which the casein was supplemented by sufficient cystine to make the total available quantity of this amino-acid equivalent to that furnished by many other proteins, likewise show that the problem of the comparative nutritive value of smaller quantities of casein is largely, if not entirely, concerned with this factor; thus, whereas with a diet containing 8 per cent of casein the total gain during the 11 weeks was only 71 gm., in contrast with 77 gm. gained on the food containing 8 per cent of lactalbumin, the addition of cystine to the same amount of casein enabled the individuals to utilize this protein for growth quite as efficiently, while the experiments lasted, as they did the corresponding quantity of lactalbumin. This is a specific result—not merely one due to some stimulating feature of amino-acids in general; for the addition of the same amount of alanine under precisely similar conditions failed to induce more rapid growth.

It seems unnecessary to reproduce here all the numerous details of these rather laborious experiments. The results are graphically presented in the form of composite curves in the appendix, Chart I. This shows in a striking way the nutrient disadvantages of too low concentrations of protein in the diet, although in view of the unlike physiological value of the different proteins ingested, a single absolute minimum intake value for a definite intensity of growth cannot be made to apply equally to all of them.⁴

Our experiments show further that exhibition of protein beyond

⁴ Obviously the unlike activity of the individual rats introduces a variable in respect to energy requirement which is beyond immediate control. This may account for the failure of many of the animals to make suitable gains in weight during the 1st week of the feeding trials. It may be that this was occasioned by exceptional activity, leading to unusual transformation of energy, as an expression of restlessness due to the conditions of limited feeding to which the animals had not yet become accustomed. According to the experience which we have presented elsewhere (*Am. J. Physiol.*, 1916, xl, 16) it may perhaps be assumed that the acceleration of growth following these temporary retardations would ultimately equalize the temporary failures to grow.

* The figures for protein do not include the small amount of protein in the water-soluble fraction.

* The figures for protein do not include the small amount of protein present in the "protein-free milk." For a discussion of this see a previous paper.¹

a certain concentration, which we have found to be approximately 12.5 per cent of the total calories, fails to increase the gains in body weight. The rats which received 19.8 and 20.5 per cent of casein and edestin respectively in their diet have not surpassed in growth those receiving food with only 16.2 and 16.7 per cent of the same proteins.

Series B.—In the series of experiments described in the preceding section the food intake of each animal was increased to precisely the same degree at the same successive interval, independent of whether the gains of weight in the different subjects were alike or not. The criticism might, therefore, properly be made that in view of the unlike rate of growth upon the same *absolute* intake of the different foods the larger animals were put at a nutrient disadvantage from the quantitative standpoint. Accordingly the actual quantitative differences between the physiological values of the different proteins would fail to be revealed to their fullest extent. The only strict basis for comparison is afforded by experiments in which the animals receive the same amount of food during the same period of time and make the same gain in weight.

Guided by our past experience we endeavored so to plan our experiments that these conditions would be fulfilled. The total food intake was increased systematically in harmony with the growth of each subject. Male rats were used. The weighed quantities of food supplied at successively increasing sizes (as indicated by body weights) were equivalent in calories to the intake determined by statistics of animals growing at a normal rate and receiving *ad libitum* a ration of essentially the same composition and energy value as those recorded in the present study.³

In order to eliminate, as far as possible, inequalities in the rate of growth of different individuals and also to be certain that no protein would be "wasted" by feeding more than the individual could actually utilize in the metabolism of growth, the concentration of *protein* in the rations of the present series was lowered so that with a sufficient total *energy* intake, the protein furnished was insufficient to permit average normal growth. Here again lactalbumin was taken as a standard with which edestin and casein (alone or with cystine or alanine) could be compared. As might

be anticipated, under these conditions of nutrition, identical in all respects except as regards the quantity of protein eaten, lactalbumin has proved itself to be quantitatively superior to both casein and edestin. *Thus, to produce the same gain in body weight 50 per cent more casein than lactalbumin was required, and of edestin nearly 90 per cent more.*

To demonstrate that in these experiments the protein was the limiting factor, comparison should be made with those experiments in which smaller quantities of casein or edestin were supplied (see Chart III). It is seen that even when the amount of these proteins considerably exceeded that of the lactalbumin, growth proceeded at a distinctly slower rate, although at corresponding sizes the same quantity of food and a relatively larger quantity of protein than of the lactalbumin was consumed.

In order to overcome inequalities in the rate of growth and food consumption, we have attempted to ascertain for edestin and casein how much the protein content of the ration in each of these respective cases needed to be increased in order to insure a rate of growth precisely equal to that upon our "standard" lactalbumin food containing 8 per cent of the added protein. Obviously when animals make the same gain of weight in the same period of time, and receive equivalent rations during each successive gain in weight, their growth will be accomplished through the same expenditure of energy and with the same intake of inorganic salts and "food accessories," the sole variable being the content of protein. This was accomplished by the use of approximately 12 per cent of casein and 15 per cent of edestin respectively. The same weight was gained as when 8 per cent of lactalbumin was used (see Chart II). The variations in the content of protein in a ration of otherwise constant energy value were made possible by substitutions of starch for protein and *vice versa* in our standard food mixture, thus not altering essentially their calorific value. The resulting make-up of the rations fed is given below.

	Protein (per cent).					
	8	8 (1 amino- acid)	10	12	13.5	15
	per cent	per cent	per cent	per cent	per cent	per cent
Protein	8	8 00	10	12	13.5	15
Amino-acid	0	0 21	0	0	0 0	0
Starch and moisture	36	35 76	34	32	30 5	29
"Protein-free milk"	28	28 00	28	28	28 0	28
Butter fat	18	18 00	18	18	18 0	18
Lard	10	10 00	10	10	10 0	10

With the lower concentrations of the other proteins used the rate of growth was in every case noticeably behind that produced by the standard lactalbumin food.

Chart II shows the composite graphs of the curves of rats receiving, in daily limited amounts, a food mixture containing 8 per cent of lactalbumin, 12 per cent of casein, or 15 per cent of edestin as its essential nitrogenous component. The results of the experiments which they represent are strictly comparable. Chart III shows the composite graphs of curves of rats similarly receiving a food mixture containing smaller proportions of casein or edestin in comparison with 8 per cent of lactalbumin. One of the curves shows the result of furnishing a larger proportion of casein (13.5 per cent).

The animals were weighed daily and were fed on the special diets when they reached a size of approximately 80 gm. During the first 3 days 5.7 gm. of food per day were given; they then received 5.8 gm. per day until a body weight of 95 gm. was attained. Thereupon the daily limited intake of food was increased after each 5 gm. of gain in weight according to the following scheme:

Body weight	Daily food intake	Body weight	Daily food intake
gm	gm	gm	gm
95-100	6 1	140-145	8 3
100-105	6 4	145-150	8 5
105-110	6 7	150-155	8 7
110-115	7 1	155-160	8 9
115-120	7 3	160-165	9 1
120-125	7 6	165-170	9 3
125-130	7 9	170-175	9 5
130-135	8 0	175-180	9 7
135-140	8 1

The detailed statistics are recorded in Table III, the weekly averages being summarized in Table IV. These show the intakes of food and protein as well as the gain in body weight totalled to the end of each successive week. The experiments of this series lasted 56 days.

An inspection of Table IV shows that the essentially equal gains made by the rats receiving 8 per cent of lactalbumin, 12 per cent of casein, and 15 per cent of edestin respectively were made with approximately equal intakes of food, namely: lactalbumin 8 per cent, 400 gm.; edestin 15 per cent, 399 gm.; casein 12 per cent, 410 gm. The diet and growth in these groups are strictly comparable, yet the total intakes of added protein to accomplish these equivalent gains in the three cases average 32.0, 59.9, and 49.2 gm. respectively. This is the most conclusive evidence which we have yet obtained of the unequal value of different proteins in growth.

In this series, as in Series A, the addition of cystine, equivalent to 3 per cent of the casein used, effected considerable economy in the availability of this protein. Thus the average results of three 8 week experiments are compared below.

Protein in food.	Total gain in weight.	Food intake.	Protein intake.
	gm.	gm.	gm.
Casein 10 per cent.....	64	385	38.5
" 8 " " + cystine.....	72	388	31.0

We thus see that the addition of cystine rendered the casein so much more efficient for growth that, on the average, 18 per cent less protein produced 12.5 per cent more growth. This capacity of cystine to supplement casein and thus increase its nutritive value is specific, depending on the chemical constitution of the amino-acid. It has been suggested that some amino-acids, such as alanine, may stimulate metabolism, thus promoting the food intake of the animal. The latter possibility has been prevented in our experiments by the control of the food supply. The replacement of cystine by alanine fails to bring about any nutritive advantage. (See Tables III and IV, casein 8 per cent + alanine.)

A comparison of the effect of supplements of alanine to the 8 per cent casein food is shown in Chart III and the tabular summaries.

Comparative Physiological Efficiency of Different Proteins in Maintenance without Growth.

When growth is not involved the requirement of protein is smaller. In consequence, inequalities between the different proteins are likely to manifest themselves less conspicuously than when continued increments of body weight augment the demand for nitrogenous foodstuffs. As the result of preliminary experiments on the protein minima for maintenance, it was stated:

"Ranges of 7 to 15 mg. of lactalbumin per gm. of rat per week represent minima lower than those found for casein, edestin, milk proteins, or gliadin, not to mention the impossibility of maintenance with zein. With the pronounced individual variations in the total food intake exhibited in our experience it is almost impossible to make precise comparisons of rats of the same size on precisely the same intake of protein. It is an obvious shortcoming of this method of procedure that the energy intake is not controlled, so that when it is large there may be a relatively greater protein-sparing effect where the non-protein nutrients are ingested in undue amounts."⁵

In order to meet objections which might arise, particularly because of the unlike daily energy intake of the subjects, further *maintenance* experiments were undertaken in which the daily food intake was limited to a fixed quantity, the protein concentration being adjusted until no essential gain or loss of body weight ensued. The absolute intake of the added protein—either casein, edestin, or lactalbumin—was calculated per gm. of animal per week in order to establish a protein minimum for maintenance in each experiment. Comparisons have been made in this way at different levels of body weight so that the factor of size might be taken into account. The total energy intake was made sufficiently liberal in accord with our experience to have permitted even considerable growth had the supply of protein been sufficient instead of minimal. In addition to the adequacy of the non-protein components of the dietary it will be observed that the inorganic constituents, as well as the food "accessories" were fed

⁵ Osborne and Mendel, *J. Biol. Chem.*, 1915, xxii, 253.

in absolutely the same amount daily.⁴ The added protein thus represented the chief variable in the experiment aside from such variations as were inevitably induced by the changing body weight of an animal kept on a fixed daily intake of food. Whenever the animals failed to eat satisfactorily, the experiment was terminated. Tables V and VI therefore contain only the statistics from successful trials. The absolute food intake in the case of the trials represented in Table VI being alike in every experiment, the latter series are therefore uniquely comparable. The periods of observation were in all cases sufficiently long to justify a decision regarding a permanent gain or loss of body weight; i.e., whether *prolonged maintenance* on the protein content under consideration was possible.

A few curves are reproduced in Chart IV to illustrate the outcome of this type of experiment. Variations in body weight amounting to no more than 2 or 3 gm. may be regarded as equivalent to a condition of maintenance. It was a common experience to observe that when animals which had been on a diet liberal in protein were fed with a ration sufficiently low in protein to approach the minimum required for maintenance they lost body weight until a sort of nutritive equilibrium was reached at a somewhat lower level. This is exemplified in Rats 3243 and 3272 (Chart IV).

Rats 3110, 3272, and 3096 (Chart IV) illustrate the low level of protein intake on which we have succeeded in maintaining such animals under strictly comparable feeding conditions with the three proteins respectively mentioned. Such observations, as well as the statistics in Tables V and VI, accordingly support our earlier conclusions regarding the comparative superiority of lactalbumin from the standpoint of protein minimum requirement.

⁴ The general composition of the food was as follows:

	per cent
"Protein-free milk".....	28
Butter fat.....	18
Lard.....	7-10
Protein.....	2.5-5.4
Starch.....	39-26
Sucrose.....	0-12

The small amount of protein in the "protein-free milk" has not been taken into account in the calculations. It is essentially the same in the different trials. For a discussion of this feature see a previous paper.⁴

CHART II. Showing that comparable gains in weight were obtained by unlike intake of three different proteins, the total food intake being the same during the same length of time—56 days. The graphs represent the composite results summarized in Table IV.

CHART III. Composite graphs of gains in weight under the comparable conditions of feeding summarized in Table IV.

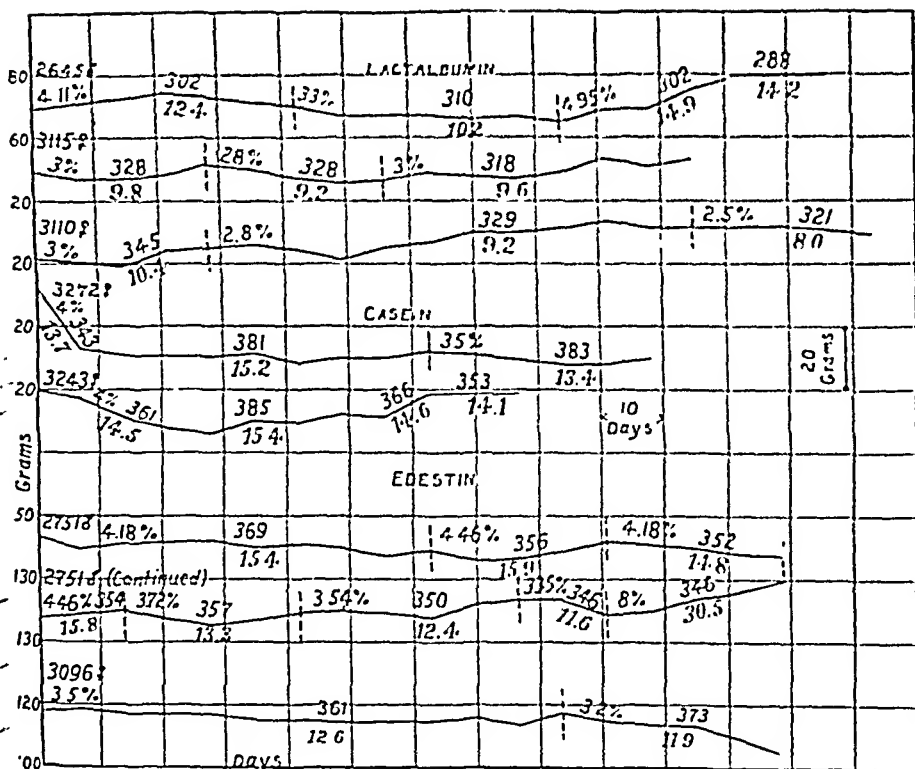

CHART IV. Illustrating changes of body weight involving successful or unsuccessful maintenance or increment of body weight on various absolute intakes of three different proteins. The nature and percentage of the protein added to the diet, together with the total food intake (above the line) and the protein intake (below the line) expressed in mg. per week per gm. of rat, are indicated on the curves.

26 Surgical Procedure and Renal Permeability

pairment of renal function leads to reduction or disappearance of the sugar in the urine with a consequent accumulation of sugar in the blood. This is in keeping with the observations on human beings recorded by Von Noorden,⁴ Lépine,⁵ and more recently by Epstein and Felsen.⁶

So that if the effect of the anesthesia and the other surgical procedures upon the kidneys is such that their function becomes impaired, it is more than likely that the failure of sugar to appear in the urine may be ascribed, at least in part, to a lessened renal permeability.

Method of Procedure.

The function of the kidneys was tested by means of phenolsulfonephthalein.

The cases selected for the study were those of simple surgical conditions in which no evidence of renal disease could be found 24 hours prior to the operation the patients received 6 mg. of phenolsulfonephthalein intramuscularly, and the time of appearance, together with the amount of the dye excreted in 1 and 2 hours, was determined. On the day of the operation the blood sugar was determined directly before the anesthesia, and again after the operation. Another dose of phenolsulfonephthalein was also injected, and its elimination in the urine observed. The blood sugar was estimated by means of the microchemical method of one of the authors.⁷ The phenolsulfonephthalein excretion was determined in the Hellige apparatus.

One of the effects of the surgical procedures common to all the cases studied was a marked diminution in the amount of urine secreted. This is undoubtedly due in part to the withholding of food from the patient prior to the operation, and to the loss of fluid from the body by sweating during the operation. Post-operative vomiting may also contribute to the loss of fluid.

The results obtained in the estimation of the blood sugar are in confirmation of those found in the work mentioned above.¹ A

FIG. 1. Showing the post-operative rise in the blood sugar and the decrease in the phenolsulfonephthalein excretion. The dotted blocks represent the phenolsulfonephthalein, the cross-lined ones the blood sugar. The shaded portion of the dotted blocks represents the difference in the excretion of phenolsulfonephthalein before and after operation. The clear area in the cross-lined blocks represents the difference in the blood sugar.

comparison of the results obtained with phenolsulfonephthalein before and after operation shows a uniform delay in the time of appearance of the dye and a decrease in the amount excreted. The reduction in the phenolsulfonephthalein elimination is very striking in some of the cases (see table and Fig. 1). The decrease in the amount of phenolsulfonephthalein eliminated after operation as compared with that prior to operation ranges from 12 to 73 per cent, the average being about 25 per cent.

SUMMARY.

Operative procedures under anesthesia cause an increase in the blood sugar content (hyperglycemia), associated with a reduction or impairment of renal function. From this it is concluded that diminished permeability of the kidneys is responsible for the infrequent elimination of sugar in the urine after operations.

A COMPARATIVE STUDY OF THE BEHAVIOR OF PURIFIED PROTEINS TOWARDS PROTEOLYTIC ENZYMES.*

By EDWARD M. FRANKEL.

(From the Sheffield Laboratory of Physiological Chemistry, Yale University,
New Haven.)

(Received for publication, June 19, 1916.)

The present day students of protein metabolism are practically in agreement in the view that a protein must be disintegrated into its component amino-acids before it can be utilized by the animal body.¹ From this standpoint the importance of the digestive process becomes paramount and its study with the newer methods correspondingly necessary. In fact, the problem of protein utilization becomes in essence a problem of the digestibility of this foodstuff by the ferments of the gastro-intestinal canal.

For the further elucidation of the phenomena of digestion two methods of research are at present available. One, the investigation of the effect of proteoclastic enzyme preparations under suitable condition *in vitro*; the other, the study of the decomposition of the protein at various stages in its passage through the alimentary canal, by the fistula methods of London and his co-workers (1910). The main advantage of the latter method lies in the fact that the conditions of the experiment simulate the natural state of affairs most closely. Yet the *in vitro* method admits of a better standardization and control of the conditions and is therefore to be preferred in a comparative study.

A large number of studies of digestion *in vitro* have been carried out by investigators in the past, but for the most part the methods employed were inadequate for the solution of the problems of modern protein physiology.²

* The data in this paper are taken from the dissertation presented by the author for the degree of Doctor of Philosophy, Yale University, 1916.

¹ Underhill, F. P., *The Physiology of the Amino Acids*, 1915.

² The earlier literature has been summed up by R. H. Chittenden in his book, *On Digestive Proteolysis*, New Haven, 1895.

The first workers concerned themselves with the changes in the solubility of the proteins as a result of the enzymatic action. Later investigators, following Kühne, became interested in the formation of proteoses and peptones. A variety of reagents were introduced for the purpose of effecting separations of the various groups, notably tannic acid, phosphotungstic acid, ammonium sulfate, and zinc sulfate (Zunz, 1899). Taylor (1907) in reviewing these methods has pointed out their shortcomings.

Physicochemical Methods.—With the advent of the physicochemical method of approach new modes of studying proteolysis were introduced. Among these were the conductivity method of Sjöquist (1895) which was later developed by Oker-Blom (1902) and Bayliss (1904, 1907). The cryoscopic depression was also used by Oker-Blom (1902). Changes in the hydroxyl ion concentrations of digestion mixtures have been used to measure proteolysis, both the gas chain and colorimetric procedures being employed. A recent development along these lines is the work of Christiansen (1912) who pointed out that the diminution of free acidity to Günzburg's reagent was an accurate measure of the extent of pepsin-hydrochloric acid digestion.

Optical Methods.—Schütz (1835) showed that changes occurred in the optical activity of digestion mixtures when proteolysis took place. Following him a number of investigators, notably Fischer and Abderhalden and their coworkers, have employed the polarimetric method. The most recent application of this is the work of Abderhalden on the detection of proteolytic ferments in the blood. Other optical procedures have been used. Robertson (1912) attempted the use of the refractometer, but without success. Hirsch (1914) showed that the interferometer could replace the polariscope. Recently Kober and Haw (1916) have brought the use of the spectrophotometer into prominence in this connection.

Colorimetric Methods.—The intensity of the biuret reaction was first suggested by Liebermann as a means of measuring the extent of proteolysis. Vernon (1903) seems to have been the first to develop this procedure successfully as a quantitative method. The most modern aspect of this method is the work of Kober and Haw (1916) who claim that by the study of the extinction coefficients at various wave lengths they can measure spectrophotometrically the quantities of the amino-acids, di-, tri-, and tetrapeptides present in a given mixture.

Triketohydrindin hydrate (ninhydrin), first brought into prominence by the work of Abderhalden (1913), has since been applied for the colorimetric estimation of α -amino-acids (Herzfeld, 1914). Harding and MacLean (1915, 1916) improved upon Herzfeld's original method and have made it more generally available for the study of proteolysis.

A number of purely chemical procedures for following the digestion of proteins have been proposed. These are of two types, and since only those which actually deal with the estimation of amino groups meet the requirements of modern studies of proteolysis, the others, such as the carbamino quotient of Siegfried and Neumann (1908) and the bromine absorption methods of Brown and Millar (1906), Auld and Moss crop (1913), and Siegfried and Reppin (1915), may be dismissed without further comment.

If we accept the concept of the structure of the protein molecule as laid down by Hofmeister and Fischer it follows that the best index of the extent to which a protein has been disintegrated is the ratio of the amino nitrogen at a given time to the total amino nitrogen obtained after complete hydrolysis. This ratio will be applicable to all proteins and is therefore well adapted for comparative work.

There are at present four methods by which the amino nitrogen of proteins and their derivatives may be estimated. The first chronologically is the "formol" titration of Sørensen (1908). This method has had a wide use; and in the study of proteolysis the most notable application has been in the investigation of Henriques and Gjalhaek (1911) who followed the cleavage of a number of proteins acted upon by acid, alkali, pepsin, and trypsin. Their experiments were carried out over long periods of time (108 days in some trials), and in the case of the enzyme experiments with a rather low ferment concentration. The data are, however, open to criticism for two reasons: their results are calculated on the basis of the total nitrogen of the proteins; and second, no account was taken of the quantities of amino nitrogen introduced with the ferments.

Van Slyke (1911, 1912, 1913) developed the nitrous acid method of estimating amino nitrogen so that it is now available for the study of digestion even where only small amounts of material are at hand. There has been some debate regarding the reliability of the method as applied to the products of proteolysis (Rice, 1915, Andersen, 1915). Abderhalden defends the accuracy of the method; and in the experience of the author the procedure has given very satisfactory results. The nitrous acid method has already found application in the proteolysis studies of Van Slyke (1911), White and Crozier (1911), White and Thomas (1912), Abderhalden and Pettibone (1912), and Berg (1916).

Attention should be called to the method proposed by Kober and Sugiura (1913). These authors find that it is possible to estimate amino nitrogen in protein derivatives on the basis of the fact that the α - and β -amino-acids dissolve a definite quantity of copper when treated with freshly precipitated copper hydroxide, and that the estimation of the copper in the complex formed is a convenient way of estimating amino nitrogen. They also point out that by an extension of their method the amino nitrogen in free amino-acids and in polypeptide linkage may be differentiated, since the copper complexes of the former are precipitated by barium hydroxide while those of the latter are not. The value of the procedure remains to be demonstrated.

The colorimetric method of Harding and MacLean (1915, 1916) of estimating α -amino nitrogen has been referred to above.

EXPERIMENTAL PART.

From the foregoing review it is apparent that for exact comparative work those procedures involving the estimation of amino nitrogen are most suitable. Of these it seemed advisable to use

the micro method of Van Slyke (1913) which has the additional advantage that it can be applied to small amounts of material. It may be argued that the methods of Kober and Sugiura and of Harding and MacLean are also applicable to small quantities; but the lack of experience with these methods made it appear as though the Van Slyke procedure, tested quite rigorously by many investigators, was on the whole best suited to the problem in hand. Since this work was begun, Harding and MacLean (1916) have published a preliminary report of digestion studies in which they demonstrated the applicability of their colorimetric method to proteolysis work.

Materials Used.—The proteins used in this study were prepared at the laboratory of the Connecticut Agricultural Experiment Station.* The pepsin used was a commercial scale preparation having considerable activity. The author is indebted to Dr. I. F. Harris for the sample of trypsin used. The erepsin employed was prepared as directed by Rice (1915) from the intestinal mucosa of the pig. This procedure yields an active solution of erepsin provided care is taken to scrape the mucosa and to place the scrapings under an antiseptic within a few hours after the animal has been slaughtered. It was found that 4 days autolysis followed by 4 days of dialysis, instead of 10 days for each process, called for by Rice, gave an active preparation which contained only very small quantities of amino pigment.

In gastric proteolysis at least two distinct factors, the pepsin and the hydrochloric acid, are involved. It might be supposed that the acid would act upon protein, causing it to be cleaved into simpler fragments with the liberation of free amino groups. Just how much of the digestion with pepsin and hydrochloric acid is due to the acid independently of the pepsin is as yet unknown. With this in mind two experiments were carried out in which the amounts of amino nitrogen liberated by pepsin and hydrochloric acid and the same concentration of hydrochloric acid alone under comparable conditions were determined.

A. Two portions of 50 cc. of diluted egg-white containing about 1 gm. of protein were mixed with an equal volume of 0.4 per cent hydrochloric acid. To one portion 20 mg. of pepsin were added. Both solutions were incubated in stoppered flasks at 38–40°C. and the amino nitrogen was estimated at intervals.

* The author desires to express his thanks to Dr. Thomas B. Osborne for his generosity in supplying these purified preparations.

0.37	24.5	
1	28.6	7.3
2	30.1	
10	47.0	9.4
58		19.0

The above tables show distinctly that *hydrochloric acid alone* in the concentrations used has very little proteolytic effect and that the cleavage taking place in peptic digestion is due primarily to the catalytic effect of the pepsin added.

Preliminary experiments indicated that simple suspension of the protein in the digestive fluid does not give satisfactory results. This is undoubtedly due, for the most part, to the difference in the surface of the protein exposed to the ferment action. Further, there was considerable difficulty in withdrawing a sample that could be regarded as uniform and at the same time leave the concentration of the solution with respect to protein unaltered. The following experiments were carried out to determine the extent of the differences that result in two parallel experiments due to inequalities in the surfaces exposed.

A. Peptic Digestion of Edestin.—In this case the protein went into solution almost immediately in both experiments so that the maximum surface was exposed to digestive action in both cases.

Two portions of 5 gm. of *edestin* were treated with 250 cc. of 0.2 per cent hydrochloric acid containing 100 mg. of pepsin and incubated in stoppered flasks at 38–40°C. Samples of 25 or 30 cc. were taken at definite intervals, neutralized with solid magnesium oxide, and treated with 5 cc. of 5 per cent colloidal ferric hydroxide and 1 cc. of 50 per cent magnesium sulfate solution, and then diluted to 100 cc. The solution was filtered and an aliquot part, 60 or 70 cc., evaporated on the water bath and then washed into the measuring burette of the amino nitrogen apparatus. The results are calculated for the 5 gm. of protein used.

Proteolysis in Solutions.

	I.	II.
	mg.	mg.
0	3.9	Lost.
4	34.2	34.2
11	46.0	47.4
19½	53.8	54.5
46	70.3	70.3

B. Two portions of 5 gm. of *edestin* were treated with 250 cc. of 0.4 per cent sodium bicarbonate solution containing 0.5 gm. of trypsin. Thymol was added as a preservative. The flasks containing the mixtures were stoppered and incubated, being shaken gently from time to time. Samples were taken at definite intervals as in the peptic digestions, and treated in the same way except that neutralization with magnesium oxide was omitted. Complete solution did not take place in the course of the experiment.

Proteolysis in Suspension.

Hrs.	Amino nitrogen.	
	I.	II.
	mg.	mg.
0	19.9	19.9
1	39.0	Lost.
3	63.0	65.7
6	86.0	90.5
11	124.0	136.5
19½	175.5	191.0
46	268.0	285.0

The data in the foregoing tables indicate clearly that *if accurate comparisons between proteins are to be made the digestions must be conducted on solutions of the proteins rather than suspensions.* The deviations may not always be as great as those obtained in Experiment B but it must be borne in mind that every precaution was taken here to have the digestions take place under strictly parallel conditions. Also with a purified protein in finely divided condition the chances for uniformity are much greater than in experiments like those of White and his coworkers (1911, 1912), Abderhalden and Pettibone (1912), and Berg (1916) where hashed tissues and finely chopped egg white were used as substrates.

Since it was not always possible to dissolve the proteins before proteolysis began it did not seem feasible, in the light of the above results, to attempt any comparative experiments with trypsin on native proteins. Instead, advantage was taken of the fact that under suitable conditions most proteins may be digested into solution with pepsin and hydrochloric acid in 3 to 6 hours so that the surface factor could be eliminated except for the slight variations that might occur in the early hours of peptic digestion. Since peptic digestion does not result in a very rapid cleavage of the protein molecule the divergences in the amounts of amino nitrogen liberated in the early hours of digestion before complete solution takes place are practically negligible. The plan of the experiments in which a large series of proteins were studied was as follows: The proteins were suspended in 0.2 per cent hydrochloric acid containing pepsin and then placed in an incubator at 38-40°C. The flasks containing the suspensions were gently agitated from time to time and when complete solution had taken place in all the flasks the sampling was begun. After the peptic digestions had run for several days and the increases from day to day were not very great, a portion of the solution was made alkaline with a slight excess of sodium carbonate and treated with trypsin. The action of the trypsin was continued for a week and then a solution of erepsin added. The amino nitrogen was estimated at intervals.

This method, in which all of the reacting material is in solution, gives the best possible conditions for adequate comparisons of the digestibility of different proteins. It is believed that the results also give a more accurate picture of the normal digestive process

in vitro than does any other type of *in vitro* experiment. The analytical data are probably accurate to within 2 or 3 per cent of the total amount estimated; so that variations of a greater magnitude among the different proteins may be regarded as significant since all the data have been calculated on a uniform basis.

Series A.—5 gm. of each of the proteins used were treated with 250 cc. of 0.2 per cent hydrochloric acid containing 0.1 gm. of pepsin and incubated in stoppered flasks at 38–40°C. At the end of 3 hours complete solution of the proteins had taken place and sampling was begun. At definite intervals 5 cc. of solution were withdrawn and treated with 0.5 cc. of N NaOH, to inhibit further peptic digestion, and then analyzed for amino nitrogen by the micro method of Van Slyke. A control experiment was run with all the reagents and ferments in the same quantities except that no protein was added. This was sampled and analyzed in the same way as were the protein digests, and the amounts of amino nitrogen found were deducted from the corresponding figures obtained on the protein solutions, so that the data recorded in the following tables are corrected for all extraneous matter that might yield nitrogen under the conditions of the analysis. After 96 hours of peptic digestion a portion of 200 cc. was withdrawn, made faintly alkaline with 10 cc. of 15 per cent sodium carbonate, and treated with 25 cc. of a trypsin solution equivalent to 0.4 gm. of dry trypsin. Tricresol was used as a preservative. The solutions were again incubated at 38–40°C. Samples were withdrawn at the stated times, treated with one-tenth their volume of glacial acetic acid to inhibit further proteolysis, and then analyzed for amino nitrogen. After a week 100 cc. portions of the tryptic digest were withdrawn and treated with 25 cc. of an erepsin solution and again incubated. Samples were taken and treated as in the case of the tryptic digest. The control experiment referred to above was carried out in the same way for the tryptic and ereptic digestions. The peptic, tryptic, and ereptic proteolyses were allowed to proceed until the experiment was stopped. The results in all cases were calculated for the 5 gm. of protein taken originally. The total amino nitrogen of each of the proteins was determined by hydrolyzing a definite amount of the substance with thirty or forty times its weight of 3 N hydrochloric acid after the method of Henriques and Gjalbaek (1910) by boiling in an autoclave at 140–150°C. for 2 hours. The hydrolysis solutions were then evaporated to dryness on a water bath to remove the excess of hydrochloric acid, and the residue was dissolved in a definite quantity of water and analyzed for amino nitrogen by the Van Slyke method. The amino nitrogen obtained on total hydrolysis was taken as the total amino nitrogen available. The data recorded in the columns "Per cent of total $NH_2 N$ " were obtained by calculating the ratio of the amounts of amino nitrogen liberated at the various stages of digestion to the total available amino nitrogen.

Series B.—This was run under conditions quite comparable with those

in Series A except that the samples for analysis were taken at different intervals. The legumelin used in this series was from vetch. The three preparations of phaseolin employed were made in different ways. NaCl indicates that the globulin was prepared in the ordinary way by extraction with salt solution and precipitated by dilution. The NaOH preparation was obtained by extraction with diluted alkali and precipitation with acid. The NaCl-NaOH sample was obtained by treatment of the NaCl preparation with alkali and acid, as in the case of the NaOH material. These different preparations were studied with a view to explaining some of the differences observed by Osborne and Mendel⁴ in feeding rats these materials as the sole protein of the dietary.

CHART B.

The data presented in the foregoing tables and curves indicate that there are no very striking differences in the extent of the disintegration, by the proteolytic ferments used, of the various proteins studied. Although the small variations noted between the amounts of amino nitrogen liberated from the different proteins at various stages of digestion may be of some significance physiologically, there seems to be no justification for this view at present. At least, there appears to be nothing in the data cited that could be used to explain the poor utilization of some of the leguminous proteins reported by Mendel and Fine (1912). While it is plausible that the defective utilization of these proteins may be due to their poor digestion *in vivo* this theory cannot be substantiated by these *in vitro* experiments. It may be that the periods during which the proteins were exposed to ferment action were too long to be comparable with the conditions that obtain *in vivo*. It has been shown that while native egg-white can be digested *in vitro* with little difficulty, when fed to a dog it is eliminated in the feces in a coagulable form (Bateman, 1916). In this case the protein leaves the stomach and intestine so rapidly that there is little or no time for the digestive ferments to act

upon it. Whether or not the same applies to the leguminous proteins is a question for further experimentation to decide.

Viewed from the standpoint of hydrolytic cleavage the results presented are of some interest in that they show to what extent proteolysis may go on in a comparatively short time as a result of mild treatment. Previous investigators have claimed that it is possible to effect complete disintegration of proteins with enzymes. The periods of digestion, however, were quite long. Here we are able to present data which show that in comparatively short periods extensive hydrolysis is possible. Peptic activity liberates about 15 to 20 per cent of the available amino nitrogen in less than 100 hours. Trypsin acting on protein partially digested with pepsin effects a cleavage equivalent to about 70 per cent in 100 to 150 hours, while crepsin acting upon material that has been digested with pepsin and trypsin can disintegrate the protein so that only 10 to 15 per cent of the amino nitrogen is in peptide linkage. The results given above are perhaps of some interest in connection with the recent controversy between Abderhalden (1915) and Andersen (1915) regarding the possibility of getting complete digestion with ferments *in vitro*. It has been shown here that in some cases over 90 per cent of the total amino nitrogen may be liberated. It is even possible that the cleavage effected is greater than this because of the fact that certain errors are introduced in not making a correction for ammonia. Possibly we are not entirely justified in the assumption that the course of ammonia liberation runs parallel to that of the liberation of amino groups. It is quite true that the figure for amino nitrogen obtained on total hydrolysis is too high when no correction is made for the nitrogen of ammonium salts. If the amounts of ammonia liberated during digestion were low we should obtain a value for the ratio of the amino nitrogen liberated to the total amino nitrogen that is low when the correction for ammonia is not applied. The net result of such a condition would probably show that the extent of proteolytic breakdown is even greater than indicated by the figures above. In this respect the data presented above support the view of Abderhalden that it is possible to disintegrate protein almost completely by the action of ferments. A consideration of the ammonia data is now being undertaken with the hope of clearing up this point.

The curve of trypsin proteolysis makes it appear that the proteolytic activity of this enzyme is practically discontinued after 100 to 150 hours. This is in all probability due to the auto destruction of the ferment.

There are few data in the literature dealing with the behavior of trypsin towards purified proteins from a strictly quantitative standpoint. Van Slyke (1911) recorded one experiment on the digestion of edestin. Henriques and Gjalbaek (1911), using the "formol" titration, investigated the tryptic proteolysis of several pure proteins. Their experiments are not comparable with those presented in this paper since they were carried out over long periods of time with much smaller ferment concentrations than were used here; and they are further not strictly comparable among themselves, since no correction was made for the amino nitrogen of the ferment preparations added. It has further been pointed out above that the results are not calculated on the proper basis. *It seemed desirable to determine how much difference in the curve of tryptic proteolysis was occasioned by a preliminary digestion of the protein with pepsin.* Furthermore, the influence of successive additions of trypsin to proteolysis mixtures was studied with the view of establishing how far cleavage with trypsin alone may go. The following plan was carried out.

5 gm. of protein were dissolved in 225 cc. of 0.5 per cent sodium carbonate solution, and 25 cc. of a solution of trypsin in 0.5 per cent sodium carbonate were added.

An amount of dry trypsin equivalent to one-tenth of the protein used was taken, as in the previous experiments. Tricresol was used as a preservative and the solutions incubated in stoppered flasks at 38-40°C. Samples were withdrawn at stated intervals, treated with glacial acetic acid to inhibit further digestion, and then analyzed for amino nitrogen. A control experiment was run and adequate corrections were made for the ferment added so that the data recorded in the tables represent the amino nitrogen actually derived from the protein used. The results are calculated for the 5 gm. of protein employed and the cleavage is given as the ratio of the amino nitrogen liberated to the total available amino nitrogen.

After 5 days of digestion a 200 cc. portion of the solution was treated with 0.4 gm. of dry trypsin dissolved in 25 cc. of water, and the proteolysis followed as before. The results were calculated for the 5 gm. of protein originally taken and are comparable with those given elsewhere in this paper.

A comparison of the data above with the results obtained when a preliminary peptic digestion was made indicates that the rate of digestion with trypsin is equally great in both cases. For example, in the case of casein the rates in the early hours are much the same in both types of digestion, the difference being found only when an examination of the later stages is made. It is shown that the same quantity of trypsin will eventually cause a much larger cleavage of the protein when a preliminary peptic digestion is made than is possible with the trypsin alone. This finding is in agreement with the observation of Fischer and Abderhalden (1903), who showed that neither proline nor phenylalanine could be obtained from the tryptic digestion of casein, while both of these amino-acids could be recovered if a preliminary peptic digestion preceded the action of trypsin.

The further addition of trypsin to a digestion mixture seems to be effective in causing further cleavage. Thus in the case of edestin the addition of more ferment caused an increase of 40 to 60 per cent in the amount of amino nitrogen liberated. The same

phenomenon was noted with the other proteins studied, though the increases were not quite so marked. The proteolysis effected by the initial quantity of trypsin is practically complete in less than 50 hours. This finding, coupled with the observation that additional trypsin can cause further degradation of the protein, appears to militate against the view of Abderhalden and Gigon (1907) regarding the inactivation of trypsin due to the binding of the enzyme by the end-products. If the end-products alone were responsible for the inactivation of the trypsin there should be no additional cleavage when more enzyme is added, for surely there must be a larger excess of end-products present over those necessary to bind the initial amount of trypsin. If the view of Abderhalden and Gigon were correct we should expect to find a definite end-point for tryptic proteolysis. Since this is not the case, as is evidenced by the results cited, it seems as though the inactivation of trypsin due to decomposition of the ferment is of greater moment than is the factor of combination with the end-products. The slight variations in dilution may presumably be ruled out because of the fact that the initial protein concentration is quite low (2 per cent). In general, where extensive cleavage is desired it would seem preferable to add small portions of ferment from time to time.

There are some data in the literature regarding the extent of proteolysis with pepsin and trypsin. However, as far as the author is aware, there are no quantitative studies of the extent to which pepsin followed by erepsin can disintegrate the protein molecule. It is generally believed that casein and gelatin are the only proteins attacked by erepsin.⁵ In the case of other proteins preliminary cleavage by some other agency must be effected. The object of the experiments cited below was to determine the effect of erepsin upon protein that was partially digested with pepsin.

⁵ On the basis of experiments with twelve proteins the author inclines to the view that erepsin may attack other native proteins. However, since the presence of trypsin in the sample of erepsin used could not be ruled out completely, though its presence was indeed doubtful (page 57), further experiments, intended to exclude the presence of trypsin, are planned. It is hoped that a report on this point will be ready soon.

3 gm. of protein were digested at 38-40°C., with 150 cc. of a 0.2 per cent solution of hydrochloric acid containing 60 mg. of pepsin. Proteolysis was allowed to proceed for 93 hours. A portion of 100 cc. equivalent to 2 gm. of protein was made alkaline with 10 cc. of 7.5 per cent sodium carbonate solution, treated with 25 cc. of erepsin solution, and incubated at 38-40°C. Samples were taken at intervals, treated with glacial acetic acid to stop further digestion, and then analyzed for amino nitrogen. The digestions were continued until no further increases of any considerable magnitude were noted. Series D and E were run under comparable conditions, but different ferment preparations were used. Control experiments were also run and corrections for the ferments introduced.

CHART C.

CHART D.

It will be noted from the tables and curves that erepsin can cause a far reaching cleavage of the protein molecule provided its action is preceded by a peptic digestion. Owing to the unlike ferment concentrations the rapidity of the cleavage varies somewhat in different preparations. The end results were, however, practically the same in the two series of digestions, the difference in action being noted only in the early hours of digestion.

Unfortunately no test was made for the presence of trypsin in the erepsin preparation used in Series D. However, the material employed in Series E, made in the same way, was tested with a flock of fibrin and no digestion was observed after incubation at 38° for 24 hours. Judging from the instability of trypsin in aqueous solution, especially on dialysis, the presence of trypsin in the erepsin solutions used (Rice's method) seems unlikely.

The desirability of having a means for effecting extensive proteolysis *in vitro* with mild treatment need not be emphasized. For such operations as the preparation of tryptophane or the isolation of other protein degradation products this method of rapidly disintegrating the protein molecule may prove of much service.

SUMMARY AND CONCLUSIONS.

It has been demonstrated that pepsin is the effective agent in pepsin-hydrochloric acid digestion since hydrochloric acid alone in the concentrations ordinarily employed has very little proteolytic effect. As a result of a series of experiments the conclusion seems justified that comparable results in proteolysis studies are to be obtained only when the substrates are in solution; otherwise deviations of 10 to 15 per cent may be encountered in duplicate experiments. An examination of the digestion of thirteen proteins shows that there is a parallelism in the cleavage curves of all the proteins, if the cleavage is calculated as the ratio of the amino nitrogen liberated at any one time to that obtained on total hydrolysis of the protein with strong acid.

Pepsin-hydrochloric acid can liberate about 20 per cent of the total amino nitrogen of a protein in less than 100 hours. Trypsin acting upon proteins partially digested with pepsin effects a cleavage of about 70 per cent. The action of trypsin upon native proteins can cause a cleavage of about 50 per cent of the peptide linkages. Further addition of trypsin may cause further disintegration of the protein.

Erepsin following the action of pepsin is a very effective agent in causing the disruption of the protein molecule. In two series of experiments cleavage of about 85 per cent of the protein could be demonstrated. The successive action of pepsin, trypsin, and erepsin liberates about 85 to 90 per cent of the total amino nitrogen of the protein studied.

The author wishes to express his thanks to Professor Lafayette B. Mendel, at whose suggestion this work was undertaken, for his advice and criticism.

THE METABOLISM OF SULFUR.

I. THE RELATIVE ELIMINATIONS OF SULFUR AND NITROGEN IN THE DOG IN INANITION AND SUBSEQUENT FEEDING.

By HOWARD B. LEWIS.

(From the Laboratory of Physiological Chemistry of the University of Illinois, Urbana.)

(Received for publication, June 7, 1916.)

The suggestion has frequently been made that a study of the ratio of the sulfur to nitrogen excretion might give valuable evidence concerning the rate of metabolism of the protein molecule, and many experimental facts on this subject have accumulated in recent years.¹ Certain observers, notably von Wendt, maintain that no true picture of protein catabolism can be obtained from a study of the nitrogen excretion alone, but only from a study of both nitrogen and sulfur excretions. In general it has been observed that the maximal sulfur elimination precedes or coincides with the maximal nitrogen elimination. From these data it has been argued that the sulfur-rich moiety of the protein molecule is split and oxidized first by the organism, while the oxidation of the sulfur-poor fraction of the molecule is delayed. A large mass of experimental data concerning the course of the excretion of sulfur and its relation to nitrogen elimination in man in starvation is also available.² Of these studies, the most recent, the record of a

31 day fast reported by Benedict,³ may be cited as typical. As the fast progressed there was a slight tendency for the ratio of the nitrogen to sulfur excretion to decrease; i.e., the excretion of sulfur became relatively higher, although the ratios tended to remain within rather narrow limits, especially toward the end of the experiments. For the fasting dog data are less numerous and confined to short periods. In two experiments extending over a period of 7 days, reported by Underhill and Kleiner,⁴ wide variations in the N:S ratio were observed although in one animal (Dog 4) the ratio was practically constant in the last 3 days of the fast (13.2, 13.5, and 13.6, calculated from the data of Underhill and Kleiner). Fasts of 3 to 4 days following ingestion of a high protein diet have been reported by Österberg and Wolf,⁵ but because of the short periods and the previous high protein diet, these figures are best interpreted as showing relative lags in the elimination of nitrogen and sulfur after the superimposition of a high protein diet. Later observations by the same experimenters⁶ included fasts of 8 days. As a result of these experiments Wolf and Österberg conclude that the organism protects the sulfur fraction of the protein molecule more effectively than the nitrogen, pointing to a special function of the cystine fraction of the protein molecule. It must be borne in mind, however, that the serum protein fed following the fasting period was higher in sulfur content than are the ordinary proteins of the diet⁷ or the proteins of the body tissue with the exception of certain albuminoids (N:S = 10.9 for the protein fed, calculated from the data of Österberg and Wolf, as compared with 14 to 15 for ordinary muscle tissue). Ingestion of such a sulfur-rich protein following fasting would tend to result in lower N:S ratios than would be obtained with a more normal diet, and would cause the contrast between the normal and fasting ratios to appear more marked

³ Benedict, *Carnegie Institution of Washington, Publication No. 223*, 1915, 277. A table comparing the results of this study with those obtained in previous studies is given on p. 279.

than would have been the case had the diet been more nearly normal for such an animal. No sulfur determinations were reported by Howe, Mattill, and Hawk⁸ in connection with a 117 day fast, the longest fast on record for the dog. No long continued fasting experiments on the dog in which the course of the sulfur elimination was followed and in which trustworthy methods for the determination of sulfur were used could be found in the literature.

McCollum⁹ has suggested on the basis of feeding experiments with swine maintained on incomplete proteins that the processes of cellular catabolism and repair do not necessarily involve the destruction and resynthesis of the entire protein molecule. If such a partial degradation of the protein molecule occurs, it would seem probable that the sulfur-containing complex would be conserved by the organism, since the sulfur requirements of the body must be supplied by organic sulfur, and since cystine is considered an essential amino-acid which must be present preformed in the diet. The central nervous system contains considerable amounts of sulfur in the form of lipoids, the exact nature of which is not clearly defined. In the organism of the dog, the demand for sulfur is presumably greater than in man, because of the large amounts of sulfur lost through the shedding of the hair. However, the sulfur-rich protein in the dog does not form a part of the more essential tissues, as the heart, nervous system, etc., which are the last to suffer loss in fasting.¹⁰ If the sulfur-containing complex can be retained for purposes of resynthesis, the withdrawal of protein (and cystine) from the diet as in fasting might result in a rise of the N:S ratio, indicating a conservation of sulfur, a rise which should become more marked as the fast progressed.

Inasmuch as there was found to be a paucity of data on the sulfur excretion by the fasting dog, such a study of a prolonged period of fasting followed by shorter periods of alternate feeding and fasting has been made, in the hope that it might prove of

¹⁰ Kumagawa, M., *Mittheil. med. Fakultät. kais. Japan. Univ., Tokio*, iii, No. 1, quoted by Lusk, G., *The Elements of the Science of Nutrition*, Philadelphia, 2nd edition, 1909, 76.

value from the point of view of a conservation of the sulfur of the protein molecule for resynthesis as discussed above. The subject of the experiments was a white female bull dog, which remained in excellent condition throughout the experiment. Water was available at all times. The animal was kept in a metabolism cage and the urine separated into 24 hour periods by catheterization. Analyses of the urine for total nitrogen by the method of Kjeldahl-Gunning and for total sulfur by the method of S. R. Benedict were made daily. In Table I for the sake of brevity the results are expressed in periods of 3 days for the most part, and the average daily elimination is given. Unfortunately no analyses were made during the first 4 days of the experiment. On the 40th day of the fast 600 gm. of beef heart¹¹ ($N = 2.85$ per cent, $S = 0.191$ per cent, $N:S = 14.9$) were fed, after which a second fasting period of 7 days followed. Beginning with the 48th day alternate feeding and fasting periods of various lengths were studied as detailed in the table.

No evidence of any increasing retention of sulfur as compared with nitrogen can be obtained from the experimental data. The $N:S$ ratios for the first and last periods of the fast (Periods 5 to 7 and 37 to 39) are practically identical, 13.9 and 14.0, respectively. The lowest ratio, 12.9, was observed toward the end of the fasting experiment (Periods 34 to 36), and the highest, 16.1, toward the middle of the fast (Periods 15 to 17). With these two exceptions the ratios vary within narrow limits, from 14 to 15 for the most part. These ratios certainly show no tendency to rise higher than the normal feeding ratios. In fact, evidence of the opposite tendency was obtained. During Periods 67 to 73, in which 600 gm. of beef heart containing 17.1 gm. of nitrogen and 1.15 gm. of sulfur ($N:S = 14.9$) were fed daily, and in which a large part of the dietary nitrogen was excreted in the urine, indicating that the urgent need for protein for repair had been satisfied (compare Periods 40 and 48 in which the same amount of food was ingested), the ratios average 17.3. This ratio is higher than is the fasting ratio. Other experiments on dogs maintained

¹¹ For the determination of total sulfur in meat the sample was heated on the water bath with concentrated nitric acid, evaporated to dryness, and Benedict's method employed. Compare Wolf and Österberg. *Biochem. Z.*, 1910, xxix, 429.

* Urine lost.

at various levels of protein intake but with the other foodstuffs also present in the diet, gave ratios averaging from 15 to 17. A protocol of such an experiment is given in Table II. If a partial

conservation of the protein molecule in cellular catabolism can be effected by the organism, as suggested by McCollum,⁹ this physiological economy would not seem to be effective in the case of the sulfur fraction of the molecule, judging from the results of the present experiment. This conclusion is in accord with the present day conception of the indispensability of adequate amounts of preformed cystine in the diet, as recently exemplified by the experiments of Osborne and Mendel¹² on white rats. Results obtained in this laboratory¹³ also indicate that dogs may be maintained in nitrogenous equilibrium on a low protein diet, poor in sulfur, with the addition of small amounts of cystine, although ingestion of the same diet without the addition of the cystine results in a negative balance.

A brief consideration of the relative eliminations of nitrogen and sulfur on ingestion of a high protein diet subsequent to prolonged fasting serves to bring out certain points of interest. On

¹² Osborne, T. B., and Mendel, L. B., *J. Biol. Chem.*, 1915, **xx**, 351.

¹³ Unpublished data.

the 40th day 17.1 gm. of nitrogen and 1.15 gm. of sulfur were fed in the form of 600 gm. of beef heart. On this and the succeeding day (fasting) there is a marked rise in the N:S ratio, indicating a sulfur retention in the organism greater than the nitrogen retention. Calculating on the basis of the ratio of the preceding period, 14.0, the elimination of 13.36 gm. of nitrogen on these 2 days should have been accompanied by the elimination of 0.945 gm. of sulfur, instead of 0.661 gm. as observed. This may be interpreted as a retention of 0.293 gm. of sulfur above the amount which would be anticipated from the quantity of nitrogen retained. All the feeding periods following fasting show similar high ratios with a like retention of sulfur. When the feeding is continued over a number of days, there results a gradual diminution of the ratio till the normal ratio is reached (compare Periods 52 to 57 and 65 to 73). If, however, the feeding period be followed by a fasting period, the ratios are lower than the normal or fasting ratios, indicating an excessive elimination of sulfur as compared with nitrogen (Periods 42 to 47, 49, 58 to 64, and 74 to 78).

These facts are capable of interpretation in two ways. The retention of sulfur may be considered as due to a lag in sulfur elimination, and the increased elimination in fasting periods subsequent to high protein periods as due to a completion of the lag excretion. But it seems hardly probable that this lag would extend throughout a period of 7 days as in Periods 41 to 47. Moreover, data on the comparative rates of sulfur and nitrogen elimination in man and dogs under various conditions of diet¹ fail to afford evidence of so prolonged a lag of sulfur behind the nitrogen. The possibility that we are dealing with a specific demand for sulfur to build up sulfur-rich proteins, that is, with a definite retention for anabolic purposes, must also be considered. On the basis of this assumption, the gradual return to normal of the N:S ratio on continued feeding would represent the rebuilding of the sulfur-rich tissues, a restoration of material lost during the starvation period. The lower ratios of the fasting periods subsequent to feeding would indicate catabolism of this sulfur-rich protein formed on ingestion of food. Until more exact figures for the sulfur and nitrogen content of the various tissues and organs are available, further discussion of this point would be of little value. We believe, on the basis of unpublished experi-

ments already referred to¹³ on the influence of feeding small amounts of cystine with a low protein diet, that this latter interpretation is correct and that we are dealing with a retention of sulfur in response to a specific demand by the organism and not with a lag in the excretion.

PHYSIOLOGY OF THE PHENOLS.*

By HARRY DUBIN.

(From the Department of Physiological Chemistry and the John Herr Musser
Department of Research Medicine, University of
Pennsylvania, Philadelphia.)

(Received for publication, June 1, 1916.)

INTRODUCTION.

The work of Baumann, Brieger, Salkowski, and others has seemingly solved the problem of the origin of phenols in urine. It is clear that the urinary phenols arise from intestinal putrefaction, and that they are derived from the tyrosine portion of the protein molecule. However, with the exception of the work of Folin,¹ little has been done—due probably to the lack of a suitable method—to determine (1) the extent to which phenols may be formed under both normal and pathological conditions, and (2) the relationship between the free and conjugated phenols. It was with these objects in view that the present work was undertaken.

HISTORICAL.

The literature has to a certain extent been reviewed by Folin,¹ so that it will be necessary only to record the results of some recent investigations.

The elimination of phenols is increased by absorption from wounds and abscesses.²

The relative ability of the various organs to dispose of phenol is as follows: liver, kidney, muscle, brain, and blood; *i.e.*, the liver has the greatest capacity for conjugating phenols, while the blood has the least. Only the epithelia of the intestinal tract give results comparable to those obtained with the liver.³ The conjugating function of the liver is not much impaired by disease.³

On starving, the phenols, after an initial fall, increase considerably.⁴ Müller⁵ reported the case of a man who showed an increase of 155 mg. of phenol on the 9th day of starvation. This was held to be due to putrefaction of intestinal secretions. If, while an animal is starving, phlorhizin be given, there is an increase in the output of phenols, but not until sugar makes its appearance.⁶ It is the increased protein breakdown, rather than intestinal putrefaction, that accounts, under these circumstances, for the increase in the elimination of phenols. Lewin⁶ observed in rabbits an increase from 6.91 mg. of phenol to 16.35 mg. of phenol per day, on giving 0.8 gm. of phlorhizin subcutaneously. In man there was an increase of two or three times the original amount of phenol upon administering 0.25 gm. of phlorhizin *per os* or subcutaneously.

It is well known that if a measured amount of phenol be ingested it cannot be recovered quantitatively in the urine, and it is believed that the missing fraction is burned. Tauber⁷ fed phenol to a dog and found that as the dose was decreased, the amount of phenol oxidized increased. Thus, he found no phenol in the fore-period, either in the urine or in the feces. On feeding 0.24 gm. of phenol in water *per os*, he found 110 mg. of phenol in the urine, and only 9 mg. in the feces. In other words, about 53 per cent of the ingested phenol was oxidized in the body through oxalic acid to carbon dioxide. Heffter⁸ states that after feeding phenol, there is an increase in phenolsulfuric acid but not in free phenol. On the other hand, Reale⁹ reports that poisoning with large amounts of phenol results in the presence of free, as well as combined, phenol in the urine.

Jonescu¹⁰ found that after feeding *p*-cresol to dogs, kept on a diet of horse meat, only about 25 per cent of the amount ingested is eliminated, and that the elimination is complete in 24 hours. Taking an average of nine persons, Siegfried and Zimmerman¹¹ showed that of the total phenols eliminated, 58.1 per cent is *p*-cresol, and 41.9 per cent is phenol. They¹² found also that *p*-cresol, fed to dogs, is largely changed to phenol. Thus, on feeding 0.5 gm. of *p*-cresol with 0.5 gm. of sodium bicarbonate on 4 successive days, 32 per cent of the total amount fed was recovered in the urine. Similarly, on feeding 0.8 gm. of *p*-cresol, 48 per cent was recovered.

The occurrence of the phenols in the urine upon disinfection of the intestine is shown in an experiment carried out by Baumann.¹³ A dog

receiving only water for 2 days was given 2 gm. of calomel on the 2nd day. As on the 4th day ethereal sulfates were still present in the urine, 2 gm. of calomel were again given. The urine of the 2 following days was free of ethereal sulfates, and gave no test for phenol or indole. On the 6th day, the dog received 5 gm. of tyrosine, but no formation of ethereal sulfates resulted; neither was there an increase of hydroxy acids.

Wohlgemuth¹⁴ fed 8 gm. of tyrosine to a rabbit and was able to recover a little less than 2 gm. of it. Dakin¹⁵ reports no increase of phenolic substances after giving tyrosine or phenylalanine. After feeding tyrosine to cats, he recovered by crystallization from the urine very small amounts of tyrosine. He found also that with smaller doses no unchanged tyrosine could be recovered in the urine. Brieger¹⁶ could find no tyrosine in the feces or urine after giving 20 gm. of tyrosine to a man weighing about 50 kilos. He did, however, find an increase in the phenols, and although the patient was constipated for 2 days after taking the tyrosine, Brieger held that the increase in phenols could not be due to constipation alone. Brieger's figures follow:

Day.	Phenol. gm.
1.....	0.0159
2.....	0.0225
3.....	0.0223
4.....	0.0182
20 gm. of tyrosine ingested in two portions.	
5.....	0.0493
6.....	0.1576
7.....	0.0851
8.....	0.0609
9.....	0.0348

Results obtained with animals and with man have led Folin¹ to conclude that the excretion of total phenol products in the urine appears to be much greater than is indicated by the phenol figures previously recorded in the literature. He shows further that the phenols are not quantitatively converted into conjugated phenols, so that the detoxication process involved in such conjugations appears to furnish only a partial protection against the toxic effect of the phenol products formed by putrefaction in the intestinal tract. Finally, the total phenol excretion tends to vary directly, but not proportionally, with the protein intake.

Some of the work described in this summary has been confirmed by our findings, while some has not. The value of our figures lies in the fact that

¹⁶ Brieger, L., *Z. physiol. Chem.*, 1878-79, ii, 241; 1879, iii, 134.

they have been obtained by a more accurate method, that of Folin,¹⁷ which permitted not only a definite quantitative determination, but also the study of the relationship between the free and the conjugated phenols.

Methods.

For phenols, free and conjugated, the technique of Folin¹⁷ was used, bearing in mind the following precautions: (a) In determining total phenols, a few glass beads should be used to prevent the liquid in the test-tube from over-boiling, during the heating just prior to placing the tube in the boiling water bath. (b) The phosphotungstic phosphomolybdic acid reagent is prepared by boiling the various chemicals with 750 cc. of water instead of 75 cc., the amount stated in Folin's description, which was an error. (c) The stock phenol solution from which the standard is prepared holds its strength for a long period of time, whereas the standard phenol solution itself deteriorates, and should therefore be prepared freshly every 4 or 5 days. (d) The color obtained with the standard solution is not absolutely blue, but has a greenish tinge. This defect is remedied by filtration, without in any way affecting the colorimeter reading. Therefore, after standing the required 20 minutes, the standard is filtered through inexpensive coarse filter paper,¹⁸ and the colorimeter readings are made at once.

With these precautions we have found the method accurate, rapid, and easy of application.

EXPERIMENTAL.

In this investigation an effort has been made to determine the behavior of the animal body, with respect to the formation and elimination of phenols, under both normal and pathological conditions. Dogs were chosen as being best suited for the work. After a period of normal observation, the animals were operated upon,¹⁹ and the desired pathological conditions produced. All operations were done under ether anesthesia. In all, eight operations were performed, two each of: (1) *Eck fistula*; (2) *intestinal obstruction*; (3) *exclusion of bile from the intestinal tract*; (4) *exclu-*

¹⁷ Folin and Denis, *J. Biol. Chem.*, 1915, xxii, 305.

¹⁸ Arthur H. Thomas Co., No. 27756, 125 mm.

¹⁹ For the operative work, I am indebted to Dr. Max Minor Peet, of the Department of Surgical Research.

sion of pancreatic juice from the intestinal tract. The technique employed in each operation was as follows:

1. *Eck Fistula*.—An artificial anastomosis between the portal vein and the inferior vena cava, with ligation of the portal vein at the hilus of the liver, was made according to the technique described by Peet.²⁰

2. *Intestinal Obstruction*.—Almost complete obstruction of the ileum was obtained about 6 inches from the ileocecal valve by detaching from the external sheath of the rectus a strip about $\frac{1}{2}$ inch wide and 1 inch long, passing it through the mesenteric attachment around the gut, overlapping, and suturing the two ends of the fascia firmly together.

3. *Exclusion of Bile from the Intestinal Tract*.—The common bile duct was tied in three places, cut between the ligatures, and part of the omentum sewed in between the cut ends to prevent a possible reunion.

4. *Exclusion of Pancreatic Juice from the Intestinal Tract*.—In one animal two ducts were found, while in another, three ducts were present. Each duct was divided between ligatures and part of the omentum interposed between the cut ends, for the reason just mentioned.

Plan of Investigation.

The general plan of the investigation was to study the daily output of urinary and fecal phenols in dogs under the conditions outlined. The elimination of phenols, under the influence of fasting, catharsis, and phlorhizin, was also studied. Inasmuch as only minimal amounts of phenol were found in the feces—amounts that could have no bearing on the final results—these determinations were dispensed with.

The dogs, kept in metabolism cages, were fed on a standard diet, calorifically sufficient, and containing about 1 gm. of nitrogen per kilo so as to make certain of an excess of food in the intestine. This diet consisted of meat, lard, bread crumbs, sugar, salt, and sufficient bone ash to insure a well formed stool. The food was mixed with 400 cc. of water, and enough additional water was given separately to bring the total daily intake up to about 600 cc. The animals were placed on this diet 3 or 4 days before the

²⁰ Peet, M. M., *Ann. Surg.*, 1914, lx, 601.

beginning of an experiment. Female dogs only were used, the urine being collected by catheter every morning at the same hour and diluted to 1,000 cc. For a time the volume of urine excreted was noted, but this was later omitted for the reason that no particular relationship was seen between the volume of urine and the amount of phenols eliminated, except as noted in Table I. The body weight was recorded daily immediately after catheterization. Tyrosine was administered *per os*, either suspended in water or mixed with the food. Phenol (Merck reagent) and *p*-cresol (Kahlbaum) were given *per os* in water.

Eck Fistula.

Experiment A-1.—Dog 15-58 (Table I). This experiment showed several interesting points. The output of phenols from day to day was quite constant, as was also the case in all of our subsequent work. Withdrawing water caused a drop in the volume of urine with a consequent rise in the output of phenols. However, it was seen that where the urine varied normally from day to day, there was little or no effect upon the phenols. After Eck fistula, the free phenols represented from 92 to 96 per cent of the total, the amount of the latter being practically unchanged. On Nov. 17, because of the presence of blood in the urine, the dog was placed on a kennel diet.

Experiment A-2.—Dog 15-58 (Table II). 2 weeks later, on Dec. 1, the regular diet was resumed, the experiment being started Dec. 6. For some reason, which we have been unable to explain—unless it is that the food is digested more rapidly—the absolute amount of total phenols was decreased in the second period, but the free phenols still represented from 96 to 98 per cent of the total. 1 gm. of phenol was fed *per os* with the result that 68.7 per cent of the amount ingested was eliminated. Both free and conjugated phenols were increased. The free phenols represented only 40 per cent of the total, indicating that the large dose of phenol had called forth, to an increased extent, the protective mechanism of the body. A second feeding gave similar results. Feeding 1 gm. of *p*-cresol resulted in the elimination of 50.6 per cent of the amount given. Here also both free and conjugated phenols were increased. The free phenols represented only 31 per cent of the total. Repetition of this feeding gave somewhat similar results. In this experiment and in all subsequent ones, it was noted that the phenol and *p*-cresol administered were eliminated entirely within 24 hours.

The results obtained on feeding tyrosine have a peculiar interest. For example, Dog 15-58 (Table II), receiving 400 gm. of meat—equivalent to 3.20 gm. of tyrosine,²¹ or 1.65 gm. of phenol—eliminated daily a total of only 0.159 gm. of phenol. However, on feeding 5 gm. of tyrosine—equivalent to 2.57 gm. of phenol—there was a rise in both free and total phenols, while the

* The figures in the first parenthesis represent "extra" phenols eliminated; those in the second parenthesis denote the output of "extra" phenols in terms of percentage of the amount ingested.

"extra" phenol eliminated was only 0.446 gm., or 17.7 per cent, of the amount ingested. In other words—and it was to be expected—tyrosine, as present in meat, did not give rise to as much phenol as did free tyrosine. Similarly, phenol, administered as tyrosine or p-cresol, did not give rise to as much phenol as did native

phenol. It was observed that tyrosine, like phenol and *p*-cresol, is eliminated entirely within 24 hours. A greater conjugation was also seen, though not as large as that produced by phenol and *p*-cresol. A slight rise in the nitrogen elimination was also noted. At no time was it possible to demonstrate unchanged tyrosine, either in the urine or the feces.

Experiment A-3.—Dog 15-58 (Table III). 1 gm. of phlorhizin rubbed up in 10 cc. of olive oil was injected subcutaneously

cumstances, in a normal dog. This is in accord with the observations of Sweet and Ringer,²² who found that upon giving phlorhizin to a dog with Eck fistula, a glycosuria resulted quite comparable to that occurring in a normal dog.

²² Sweet, J. E., and Ringer, A. I., *J. Biol. Chem.*, 1913, xiv, 135.

In fasting, as was to be expected, there was a diminution in both total and free phenols, the latter amounting to 74 per cent of the total. A greater ability to conjugate was shown, but no initial fall and subsequent rise in the phenol excretion as described by Herter⁴ and Müller⁵ was noted. Neither was it possible, by giving calomel, to rid the urine entirely of phenols. In this connection, it is interesting to recall that Baumann,¹³ owing perhaps to the inadequacy of the prevailing methods, could get no test for phenols after administering calomel to a fasting dog.

Experiment G.—Dog 16-56 (Table IV). The results of this experiment are in accord with those obtained in the previous Eck fistula dog. After the operation there was a tendency for the total phenol elimination to decrease, due perhaps to a more rapid rate of digestion. The influence of tyrosine before and after the operation is about the same—if anything, for the reason just mentioned, less total phenols are obtained from the same amount of tyrosine after the operation than before.

Influence of Tyrosine, Phenol, and p-Cresol on Phenol Excretion in Normal Dogs.

Experiments K and M.—Dogs 15-74 and 16-20 (Table V). In general the findings here corroborated those of Experiment G.

Exclusion of Pancreatic Juice from the Intestinal Tract.

Experiment B-1.—Dog 15-63 (Table VI). The normal figures recorded here are in accord with those of Tables II and V.

Experiment B-2.—Dog 15-63 (Table VII). This experiment corroborates fully Experiment A-3 (Table III). While the results in the latter experiment were observed in a dog with Eck fistula, those of the present experiment were noted in a normal dog.

Experiment B-3.—Dog 15-63 (Table VIII). Several differences were noted between the results of this experiment and those of Experiment B-2 (Table VI). After the operation, the total amount of phenols eliminated was increased, resulting in a greater conjugation. On administering tyrosine, a greater percentage was eliminated as phenols. Undoubtedly this was due to the fact that the absence of pancreatic juice from the intestinal tract retarded the processes of digestion. The administration of phenol and of p-cresol resulted in a lessened elimination; *i.e.*, with phenol, there was a drop from 75.8 per cent to 51.1 per cent of

Intestinal Obstruction.

Experiment C.—Dog 16-6 (Table X). The results obtained before the operation are in accord with those found in normal dogs. After the operation, it is worthy of note that although the animal ate practically nothing, the formation and elimination of phenols rose to a high level, the free phenols representing only 56 per cent of the total. In other words, the conjugation, due to the larger amounts of phenols present, was increased just as though a dose of phenol had been ingested. It was noted also that on giving phenol after the operation, only 51 per cent was eliminated, while before the operation the output was 64 per cent. This is explained on the ground that digestion is markedly retarded. In this respect the results were somewhat similar to

TABLE X.

those obtained before and after the exclusion of pancreatic juice from the intestinal tract. On March 27, when the animal was chloroformed, the intestine was found to be dilated to about 100 times the normal capacity for about 3 feet above the obstruction; this dilatation continued in a lesser degree up to the jejunum. The jejunum and duodenum were normal. It would appear that almost complete obstruction had been obtained.

there was an increase in the formation and elimination of phenols the free phenols represented 80 per cent of the total, as against 75 per cent before the operation. In all other experiments, an increase in the phenol formation was accompanied by a decrease in the output of free phenols, figured as per cent of total, while in this experiment and in the following one the reverse was the case. Of the ingested phenol and *p*-cresol, 43.3 per cent of the former and 25.5 per cent of the latter were eliminated after the operation as against 54 and 42.8 per cent, respectively, before. Feeding tyrosine caused an increased conjugation, the free phenols dropping from 75 to 54 per cent before the operation, and from 80 to 75 per cent after. It was observed, however, that only 14.8 per cent of the ingested

tyrosine was eliminated before the operation as against 19.8 per cent after. This was similar to the result obtained with tyrosine after excluding the pancreatic juice, and, as in the latter case, may be explained on the basis of delayed digestion.

Experiment E.—Dog 16-41 (Table XIII). The results of this experiment were not as clean cut as they might be, for the animal refused to eat and was rather sick. On autopsy the bile duct, up to the point tied, was greatly enlarged.

DISCUSSION.

The formation of phenolsulfuric acids is one example of the ability of the body to convert poisonous substances into harmless compounds. It is, however, an open question as to whether this power of the body is sufficient for all purposes. Since the time of Baumann it has been believed that phenols were quantitatively converted into harmless phenol esters; hence phenols were estimated on the basis of conjugated sulfates, whereas our figures corroborate the statement made by Folin¹ that the greater part of the phenols are excreted unconjugated.

It has been thought that the free phenols are harmful to the body, and this must be due primarily to an increase of total phenols, with its accompanying increase of free phenols. For example, it is seen in normal cases that the absolute amount of free phenols represents from 75 to 85 per cent of the total. On the other hand, where there is a rise in total phenols, whether due to ingested phenols or to some pathological condition, the free phenols, although increased absolutely, represent from 30 to 70 per cent of the total. In other words, the absolute amount of free phenols should be taken into consideration together with the percentage in considering their deleterious influence.

With one exception, an increase in the formation of phenols, whether normal or pathological, resulted in an increased conjugation, though the reverse might have been expected. It would appear that the protective mechanism of the body responded to the greater stimulus. The exception noted was in the case where bile was excluded from the intestinal tract. Here there was an increased phenol formation accompanied by a decreased conjugation. It would seem, therefore, that the bile plays some part in assisting the liver in its conjugating function.

There is a *greater conjugation* after feeding *p*-cresol than after giving phenol. In view of the fact that *p*-cresol makes up the larger part of the urinary phenols, it seems plausible to assume that when it is introduced into the body it is more easily conjugated. Hence on feeding this substance the elimination of free phenols rises only very little.

The high percentage of free phenols prevailing after Eck fistula was to be expected, inasmuch as the liver, which is the main seat of conjugation, has been cut out of the circulation. In spite of this, upon the ingestion of phenol there is an increased conjugation, showing that other organs, when necessary, can take up the work of the liver in this respect.

Lewin⁶ held that the increased protein breakdown accounted for the increased phenol formation when phlorhizin was given. While it is true that phlorhizin causes a protein breakdown, it is highly improbable that this is the reason for an increased phenol production. Regarding the fate of phlorhizin in the body, it has been shown²³ that when injected, part of it is eliminated as a combined glucuronic acid while another part apparently undergoes further change; also, unchanged phlorhizin can be found for some time in the blood and tissues. In view of all this, when it is considered that phlorhizin contains two benzene radicals, and that benzene when fed¹ gives rise to phenol, it seems likely that it is the phlorhizin *per se* which is converted into phenol.

The results obtained show, among other things, that gastrointestinal disturbances, in which it is reasonable to assume that there is an increase in the formation of phenol, and also certain liver diseases, where it is supposed that the mechanism for the detoxication of phenols has been impaired, offer a field for investigation, for, as Folin¹ points out, and as this work proves, the phenols can be taken as an index of intestinal putrefaction.

SUMMARY.

The results of this investigation, in addition to confirming the findings of Folin,¹ bring to light some interesting observations.

A. 1. The elimination of phenols from day to day is quite constant.

²³ Von Fürth, O., *Chemistry of Metabolism*, Philadelphia, 1916, 280.

2. Withdrawing water from the diet causes an increased phenol elimination.

3. After Eck fistula, the free phenols represent as high as 97 per cent of the total, the latter, as also the former, exhibiting a tendency to decrease.

4. After intestinal obstruction, there is an increase in both free and total phenols, the former constituting as low as 55 per cent of the latter.

5. In pancreatic insufficiency, there is an increase in both free and total phenols with an accompanying decrease in the percentage of free phenols.

6. After excluding the bile, both free and total phenols increase, but with an increase in the percentage of free phenols.

B. 1. The feeding of phenol and *p*-cresol results normally, with but slight variations, in the elimination of about 65 per cent and 40 per cent respectively.

2. After Eck fistula, about the same excretion is noted.

3. After intestinal obstruction, pancreatic insufficiency, and exclusion of bile, there is in both cases a drop in the amount excreted.

C. 1. The feeding of tyrosine results normally in an excretion of about 14 per cent, as phenols.

2. After Eck fistula, practically the same amount is eliminated.

3. After exclusion of bile and pancreatic juice, about 20 per cent of ingested tyrosine is eliminated.

D. Feeding of any of the three substances causes an increase in the conjugation at all times—*p*-cresol to a greater degree than phenol, and the latter to a greater extent than tyrosine.

E. Tyrosine, phenol, and *p*-cresol, fed in amounts of 5 gm., 1 gm., and 1 gm. respectively, were all eliminated within 24 hours.

F. No unchanged tyrosine could be demonstrated in the urine or feces.

G. Fasting reduces the phenols to a low level; the injection of phlorhizin during fasting causes an increase in the output of phenols.

H. It is impossible to free the urine entirely of phenols by the use of calomel.

I. The bile appears to have some influence on the conjugating function of the liver.

J. The phenols can be taken as an index of intestinal putrefaction.

THE INFLUENCE OF INGESTED CARBOHYDRATE, PROTEIN, AND FAT ON THE BLOOD SUGAR IN PHLORHIZIN DIABETES.

BY FRANK A. CSONKA.

(From the Laboratory of Dr. J. P. McKelvy, Pittsburgh.)

(Received for publication, June 14, 1916.)

INTRODUCTION.

By introducing glucose solution into a normal animal, an increase in blood sugar occurs which lasts but a short time and the normal level for blood sugar is then reestablished. The destination of the absorbed sugar is not yet known. The possibilities are that, after passing through the intermediary stages of metabolism it is burned; or it is distributed in the body as glucose; or is converted into glycogen and deposited in the tissues; or is eventually converted into fat. In the phlorhizinized dog the above mentioned possibilities are limited to the temporary deposition of glucose or glycogen since the ingested glucose reappears practically quantitatively in the urine. On studying the velocity of the elimination of the "extra glucose," it was found that of 16 gm. of glucose ingested, 94 per cent was excreted in the urine during the first 5 hours, and that the maximum amount appeared during the 2nd and 3rd hours.¹ The endogenous glucose derived from glycine and alanine was eliminated almost as rapidly as the isoglucogenic quantity of exogenous glucose.

The purpose of this paper is to show the influence of ingested carbohydrate, protein, and fat on the blood sugar in phlorhizinized animals; the blood sugar being determined in hourly periods to compare the rate of absorption of glucose, both of exogenous and of endogenous origin, to the rate of elimination determined by means of "extra glucose" mentioned above.

¹ Csonka, F. A., *J. Biol. Chem.*, 1915, xx, 539.

ingestion of 50 gm. of glucose, (A) in the phlorhizinized dog, and (B) in the normal dog.

A marked hyperglycemia is found in the phlorhizinized dog, but in the normal dog the blood sugar remains practically at the normal level. In both cases the stomach contents showed a positive glucose reaction. In the former (A) it was impossible to determine the glucose quantitatively on account of the loss of the stomach contents by killing. In the latter case (B), in 310 cc. of stomach contents, the glucose amounted to 15.92 gm.

In Table III are collected the results of experiments performed on phlorhizinized dogs fed glucose, meat, gelatin, and lard.

TABLE III.

Experiment.	Date.	Dog.		Fed.	Blood sugar (in percentages).						
		No.	Weight. kg.		Before feed- ing.	After feeding.

* Second phlorhization.

Except in the case of dogs fed lard (which represents fat in general) all show an increase in blood sugar; but the increase following the ingestion of 20 gm. of glucose, for example, is greater than that following the ingestion of 200 gm. of meat, though they represent approximately isoglucogenic quantities.⁷

⁷ Compare Janney, N. W., and Csonka, F. A., *J. Biol. Chem.*, 1915, xxii, 203.

DISCUSSION AND CONCLUSION.

Following the ingestion of 20 gm. of glucose the blood sugar reached the maximum at the 2nd hour, and declined to the original level at the 4th hour. In an earlier experiment,¹ it was shown that of 16 gm. of glucose given to a phlorhizinized dog, 94 per cent was excreted during the first 5 hours as "extra glucose." The curve of the blood sugar content runs parallel with the curve of the "extra glucose." Since the elimination of ingested glucose is practically complete and the curve of blood sugar runs parallel

FIG. 1. The curves represent the blood sugar content after the ingestion of carbohydrate (—), protein (----), and fat (.....). The number of the curve corresponds with the number of the experiment.

to that of "extra glucose," the conclusion is reached that no glucose was deposited between the periods of absorption and elimination. The only difference observed in the blood sugar content after the ingestion of large quantities of glucose in a more concentrated solution (50 gm. of glucose in 150 cc. of water) is that the hyperglycemia is maintained for a longer period of time (Fig. 1). That the blood sugar is increased after ingestion of protein is apparent from the curve which shows that the endogenous glucose derived from meat protein and gelatin appears in

the blood as glucose—at least, partially so—since the isoglucogenic quantities of ingested endogenous and exogenous glucose should give the same increase of blood sugar. The ingestion of fat, which does not produce “extra glucose,” did not cause any appreciable increase in blood sugar.

RESEARCHES ON PYRIMIDINES.

LXXIX. THE SYNTHESIS OF THYMINE-4-ALDEHYDE.

BY TREAT B. JOHNSON AND LEONARD H. CRETCHER, JR.*

(From the Sheffield Chemical Laboratory, Yale University, New Haven.)

(Received for publication, June 6, 1916.)

The pyrimidine-nucleoside investigations which have been carried on in the Sheffield Laboratory by Johnson and his co-workers have been confined to a study of uracil and thymine combinations containing monatomic primary alcohol groupings in the 4-position of the pyrimidine ring. Two simple representatives have thus far been described in the literature; namely, the simple mono-nucleosides of uracil and thymine as represented by Formulas I and II respectively. The corresponding nucleoside of the aminopyrimidine cytosine (III) has not been prepared.

The only method of synthesis which has proven feasible thus far for the preparation of pyrimidines leading to nucleoside combinations of the above type is that involving the condensation of thiourea with certain β -ketone esters. Ethyl γ -ethoxyacetoacetate (IV) is the simplest representative of the class of ketone esters utilized in this work, and by interaction with thiourea leads to the formation of the 2-thiopyrimidine (V). The latter is easily converted into the uracil-nucleoside (VI), as has been shown in a previous paper by Johnson and Chernoff.¹

* Part of a Dissertation presented to the Faculty of the Graduate School of Yale University in candidacy for the degree of Doctor of Philosophy, 1916.

¹ Johnson, T. B., and Chernoff, L. H., *J. Am. Chem. Soc.*, 1914, xxxvi, 1742; 1913, xxxv, 585; *J. Biol. Chem.*, 1913, xiv, 307.

In order to extend the application of our method and obtain higher homologues of these simple nucleosides, or pyrimidine combinations containing secondary alcohol groups, we have prepared several representatives of a new type of β -ketone esters corresponding to VII. Such combinations condense normally with thiourea giving 2-thiopyrimidines (VIII), and the latter are desulfurized easily by digestion with chloroacetic acid with production of their corresponding ethers represented by IX. To our surprise, however,

when we attempted to hydrolyze these ethers (IX) to their corresponding alcohols (X), we obtained very abnormal and unexpected results. Products were obtained which possessed none of the properties of the desired pyrimidine nucleosides, and the data thus far obtained lead us to the conclusion that pyrimidine combinations of this type (X) cannot be made by this method. The experimental evidence supports the assumption that such secondary alcohol combinations are transformed by hydrolysis into representatives of an entirely different class of cyclic compounds.²

² The results of this investigation will soon be published in a paper from this laboratory by Treat B. Johnson and Sidney E. Hadley.

In the light of these new and unexpected results it was therefore necessary to direct our attention to the preparation of pyrimidines carrying an aldehyde group in the 4-position of the ring; in other words, to synthesize the aldehydes of uracil and thymine (XI and XII). Such combinations should theoretically interact with Grignard's reagents with formation of the desired pyrimidine nucleosides containing secondary alcohol groups. A transformation of this character would be represented by the following equation:³

A method has now been developed whereby such aldehyde combinations can be synthesized easily and in quantity. The complete synthesis of uracil aldehyde (XI) has already been described by the writers⁴ and in this paper we shall give a description of the synthesis and properties of the corresponding aldehyde of thymine (XII) and also several of its derivatives.

The nearest approach to an aldehyde synthesis recorded in the pyrimidine literature, previous to the developments in this laboratory, is that involving a reaction described by Behrend.⁵ He made the interesting observation that amidomethyluracil (XIII) is transformed very smoothly into the oxime of diazouracil-4-aldehyde (XIV) by the action of nitrous

³ The investigation of the behavior of Grignard's reagents towards pyrimidine aldehydes will be taken up this coming year.

⁴ Johnson, T. B., and Cretcher, L. H., *J. Am. Chem. Soc.*, 1915, xxxvii, 2144.

⁵ Behrend, R., *Ann. Chem.*, 1888, ccxl

acid. This oxime was isolated in a crystalline condition and was characterized by its remarkable stability. On reduction with stannous chloride in hydrochloric acid solution it was transformed into a compound isomeric with xanthine (XVI). Behrend called this substance *Isoxanthine* and suggested the following expression as a possible explanation of the mechanism of the transformation. The intermediate product—hydrazinouracil-aldehyde (XV)—was not isolated.

The first pyrimidine aldehydes actually isolated were 2-thiouracil-4-aldehyde (XIX), 2-ethylmercapto-6-oxypyrimidine-4-aldehyde (XX), and uracil-4-aldehyde (XXI), which were synthesized by Johnson and Cretcher.⁴ Their method of introducing the aldehyde group into the pyrimidine ring differs from any which has hitherto been employed for the synthesis of heterocyclic aldehydes. It is based on the observation that esters of the type α -ethyl γ -diethoxyacetoacetate (XVII) condense normally with thiourea giving the corresponding diethylacetals of 2-thiopyrimidin aldehydes. The ester (XVII) interacts, for example, with thiourea forming the acetal (XVIII) which can be transformed easily by hydrolysis into the aldehyde of 2-thiouracil (XIX). The aldehyde combinations described proved to be extremely reactive.

They interacted normally with phenylhydrazine, and possessed a remarkable capacity of adding water, which could not be removed without heating at high temperatures.

Dakin and Dudley⁶ have shown that the ketone ester—ethyl γ -diethoxyacetoacetate (XVII)—interacts normally with methyl iodide, in the presence of sodium ethylate, giving the corresponding methyl derivative (XXIII). We find that the same ketone ester is easily obtained in good yield by application of a Claisen condensation with ethyl diethoxyacetate and ethyl propionate (XXII). When this substance is brought into alcohol solution with thiourea and sodium ethylate it behaves in a similar manner as its lower homologue (XVII) and interacts with the thiourea forming the acetal of 2-thiothymine-4-aldehyde (XXIV). The yield is excellent. This acetal behaves exactly as its uracil analogue except that it is less soluble in hydrochloric acid solution. It dissolves in alkaline solutions without decomposition and is reprecipitated unaltered from such solutions by the addition of acids. When warmed with acids, both mineral and organic, it is easily hydrolyzed with formation of 2-thiothymine-4-aldehyde (XXVII). This compound crystallizes from dilute hydrochloric acid with a molecule of water and is characterized by its remarkable stability.

⁶ Dakin, H. D., and Dudley, H. W., *J. Chem. Soc.*, 1914, cv, 2453.

The 2-thioacetal (XXIV) undergoes alkylation quantitatively with ethyl bromide in alcohol solution, and in the presence of the required amount of sodium ethylate, giving the mercaptopyrimidine (XXV). This acetal is extremely unstable in the presence of acids and is even hydrolyzed by acetic acid, in the cold, with formation of the corresponding mercaptopyrimidine aldehyde (XXVI). This new aldehyde is a beautiful crystalline substance, but is not so active a reducing agent as the corresponding oxygen and sulfur aldehydes. It does not reduce Fehling's solution and reduces silver nitrate in alkaline solution with difficulty.

When the mercaptopyrimidine (XXV) is heated with hydrochloric acid, not only the acetal grouping is affected but the mercapto group undergoes hydrolysis as well, with liberation of ethylmercaptan, and thymine-4-aldehyde (XXVIII) is formed. It is necessary, however, to digest for a long time to remove the mercapto radical completely. During the course of this prolonged treatment the aqueous solution is not discolored but remains bright yellow, and no amorphous or resinous decomposition products are formed. This behavior is quite different from that observed during the hydrolysis of the corresponding mercapto-6-oxypyrimidine-4-aldehyde.⁴ Uracil aldehyde is much more sensitive to the action of acids than thymine aldehyde (XXVIII). Thymine aldehyde reduces Fehling's solution, but does not undergo oxidation when exposed to the air, nor did it oxidize in hydrochloric acid solution when the latter was exposed to the atmosphere for 2 weeks.

The tendency to combine with the solvent from which it is crystallized was observed in the case of thymine aldehyde as well as with uracil aldehyde. The thymine derivative crystallizes from aqueous solution with one molecule of water and when it separates from alcohol carries one molecule of this reagent. Both forms are easily dissociated on heating. The changes described above are represented by the following formulas:

The normal class reactions, which are generally characteristic of combinations containing the aldehyde group, can be applied successfully with the three pyrimidines XXVI, XXVII, and XXVIII. All combine with phenylhydrazine giving phenylhydrazones and likewise interact with hydroxylamine forming the corresponding oximes. The latter compounds are formed in good yield and should be of value for further synthetical work. Thiothymine-4-aldehyde (XXVII) and thymine-4-aldehyde (XXVIII) interact smoothly with aniline with formation of their corresponding anils. The aldehyde group in the pyrimidine (XXVI) undoubtedly interacts with aniline in a similar manner, but it was impossible to control the reaction, so that the corresponding mercaptopyrimidine-anil could be isolated. The mercapto group of the pyrimidine is removed at the same time with production of ethylmercaptan. The investigation of pyrimidine aldehydes will be continued.

EXPERIMENTAL PART.

Preparation of Ethyldiethoxyacetate. $(C_2H_5O)_2CH.COOC_2H_5$.—

This ester was prepared by the esterification of diethoxyacetic acid according to the method of Wohl and Lange⁷ and also from the silver salt of this acid by boiling an ether suspension of the salt with ethyl iodide. The latter method gave a better yield of the ester and a description of one experiment will illustrate the procedure followed. Three molecular proportions of sodium (56.2 gm.) were dissolved in 800 cc. of absolute ethyl alcohol. The flask containing the ethylate solution was connected to a reflux condenser and heated on a water bath. To this solution one molecule of dichloroacetic acid (105 gm.) was slowly added through a dropping funnel. Sodium chloride at once separated from solution; the sodium salt of diethoxyacetic acid, being very soluble in alcohol, remained in solution. After addition of all the dichloroacetic acid the sodium chloride was filtered off and the clear solution again heated on the water bath for 3 hours. Sodium chloride again separated and the solution was again filtered. The combined residues of sodium chloride, when dry, weighed 95 gm., an amount corresponding to that required for the completed reaction. The alcohol was removed under reduced pressure, a dark colored pasty mass remaining in the flask. This crude sodium salt was dissolved in 150 cc. of water and the solution filtered. The solution was transferred to a large beaker, cooled with ice water, and a cold solution containing 145 gm. of silver nitrate (in 200 cc. of water) gradually added. There was at once precipitated a voluminous, non-crystalline mass of the silver salt of diethoxyacetic acid which was filtered free from water by suction. The filtrate was evaporated to dryness under reduced pressure and the residue combined with the main portion of the salt. This was then dried in a vacuum desiccator over concentrated sulfuric acid.

Conversion of the Silver Salt into Ethyldiethoxyacetate.—The dry salt obtained above was suspended in 400 cc. of dry ether and 145 gm. of ethyl iodide were added gradually through a dropping funnel. After all the iodide had been added the containing flask was heated in a water bath for 4 hours. The solution was filtered

⁷ Wohl, A., and Lange, M., *Ber. chem. Ges.*, 1909, xli, 3612.

and the silver iodide washed several times with dry ether. After removal of the ether, the almost colorless oil was distilled *in vacuo*. The yield was 93 gm. of pure ester, boiling between 94 and 98° at 19 mm. pressure. This amount corresponds to 65 per cent of the theoretical.

Ethyl α -Methyl- γ,γ -diethoxyacetoacetate (XXIII).—This ester was first prepared by Dakin and Dudley⁶ by heating the sodium salt of ethyl diethoxyacetoacetate with methyl iodide. The ester used in this investigation was prepared by the action of sodium on a mixture of ethyl diethoxyacetate and ethyl propionate. The proportions taken were as follows: 65 gm. of diethoxyacetic ester, 110 gm. of ethyl propionate, and 24 gm. of sodium wire. All of the diethoxy ester and one-half of the propionic ester were mixed in a flask, connected with a reflux condenser, and heated to about 80°. One-half of the sodium was then gradually added. After about 3 hours the sodium had all reacted and the remainder of the propionic ester was added, after which the remainder of the sodium was introduced into the flask in small amounts at a time, as before, the heating being continued during the entire process. After the last of the sodium was added the temperature of the mixture was kept at 80° for 4 hours longer or until the sodium had practically disappeared. The mixture was then allowed to cool and ice water was added to dissolve the sodium salt of the β -ketone ester. The solution was transferred to a large separatory funnel and the unaltered esters were removed by extraction with ether. Much ether was now added and the lower aqueous layer made acid to litmus with cold dilute hydrochloric acid, and the layers separated. After three extractions with ether the water layer became colorless. The ether solution was finally washed with dilute sodium carbonate solution and dried for 6 hours over desiccated sodium sulfate. After removal of the ether the ester was obtained as a red oil and was distilled in a vacuum. When the temperature of the bath was raised to 145–155°, at a pressure of 17 mm., a few gm. of liquid distilled over from 90–112°. This fraction consisted of unchanged esters not removed by ether. When oil ceased to come over the temperature of the bath was raised to 175°. 20 gm. of colorless oil now distilled at 130–140°, the pressure remaining constant at 17 mm. With the bath at 180° and the pressure at 18 mm. 40 gm. more of the "

distilled over at the constant temperature of 140° . Dakin and Dudley's product boiled between 110 – 112° at a pressure of 4 to 6 mm. The total yield of purified ester was 60 gm., corresponding to 70 per cent of the theory, based on the quantity of the diethoxy-acetic ester used. The yield obtained by Dakin and Dudley was also 70 per cent. This ester is colorless and has a pleasant odor.

0.1506 gm. substance gave 0.3130 gm. CO_2 and 0.1160 gm. H_2O .

2-Thio-4-diethoxymethyl-5-methyl-6-oxypyrimidine (XXIV).—

This compound is easily obtained in the following manner. 9 gm. of sodium were dissolved in 200 cc. of absolute alcohol and 40 gm. of thiourea dissolved in the resulting solution. Next 51 gm. of the β -ketone ester, described above, were added and the mixture was heated on a water bath for 6 hours, after which time it was transferred to a casserole and the alcohol evaporated by heating on a steam bath. The residue was light yellow. It was dissolved in about 300 cc. of water, cooled, and the solution acidified with acetic acid. On adding the acid a colorless oil was obtained which readily became crystalline when stirred. The product was colorless, weighed 50 gm., and partially melted at about 119° . There was some thiourea present and the melting point was not sharp. The entire amount was crystallized from hot 50 per cent alcohol from which it separated on cooling, in large blocks which melted between 119 – 120° : 33 gm. of pure pyrimidine were thus obtained and 6 gm. more on concentration of the mother liquor.

This pyrimidine is slightly soluble in water and very soluble in alcohol.

Calculated for $\text{C}_{11}\text{H}_{10}\text{O}_3\text{N}_2\text{S}$: N, 11.4. Found: N, 11.4.

In order to obtain this product in pure form it is not necessary that the β -ketone ester be isolated and purified by distillation. In fact, the reaction with thiourea was first brought about with the crude undistilled ketone ester. The method was as follows: The lower boiling esters present as impurities in the crude mixture

were removed by heating the containing flask to 150° in an oil bath at 17 mm. pressure. After liquid ceased to distil under these conditions the dark red oil remaining was condensed with thiourea under the exact conditions described above. In order to obtain the final product perfectly colorless it is necessary, however, to make several recrystallizations from alcohol.

2-Thio-5-methyl-6-oxypyrimidine-4-aldehyde (2-Thiothymine Aldehyde) (XXVII).—A quantitative yield of this aldehyde is obtained by hydrolysis of its acetal with hydrochloric acid. The acetal was dissolved in hot dilute acid (1:1) and the solution evaporated to dryness on a water bath. During the course of the evaporation the color of the solution gradually became bright yellow. The powder remaining after the evaporation was yellow and melted to a dark oil at 232° with effervescence. It is soluble in hot water, alcohol, and acetic acid, and is more soluble in dilute hydrochloric acid than in water. When crystallized from alcohol the aldehyde is colorless, but upon being heated again becomes yellow. After crystallization from alcohol the melting point is $232\text{--}233^{\circ}$. The aldehyde when prepared by evaporation to dryness with hydrochloric acid does not carry water of crystallization.

Calculated for $C_6H_6O_2N_2S$: N, 16.4. Found: N, 16.3.

When allowed to crystallize slowly from dilute hydrochloric acid the aldehyde contains one molecule of water of crystallization.

Calculated for $C_6H_6O_2N_2S \cdot H_2O$: N, 14.8. Found: N, 14.6.

This aldehyde reduces an ammoniacal silver nitrate solution but not Fehling's solution.

Derivatives of 2-Thiothymine-aldehyde. Phenylhydrazone.—Thiothymine aldehyde was dissolved in hot dilute acetic acid and phenylhydrazine added to the solution. The hydrazone separated at once as a yellow crystalline mass. It crystallizes from glacial acetic acid in long prismatic needles which darken around 265° and melt at 287° with effervescence. The compound is insoluble in water and only sparingly soluble in alcohol.

Oxime.—0.6 gm. of sodium hydroxide was dissolved in 10 cc. of water, 1 gm. of aldehyde dissolved in the alkaline solution, and 0.4 gm. of hydroxylamine hydrochloride was added. The solution

was allowed to stand over night at room temperature. The sodium salt of the oxime separated as a white powder but was not filtered off. This salt was converted to the oxime by the addition of just sufficient glacial acetic acid to give an acid reaction to the solution when tested with litmus. After stirring and allowing to stand for a few minutes the oxime was filtered off and recrystallized from glacial acetic acid, from which it separated in hexagonal plates which decomposed at 233° . The yield was 1 gm.

Calculated for $C_6H_7N_3O_2S$: N, 22.7. Found: N, 22.4.

This oxime is difficultly soluble in hot alcohol and glacial acetic acid, and almost insoluble in hot water.

Anil.—To prepare this Schiff base 1 gm. of the thioaldehyde was mixed with 5 cc. of aniline in a test-tube, and the mixture heated in a water bath for several hours. The aldehyde did not dissolve in the hot aniline. The color of the reaction mixture soon became a bright yellow. Ether was then added, after cooling, to remove the excess of aniline, and the solid filtered off. The anil was obtained as a yellow compound, insoluble in water or alcohol, and difficultly soluble in hot glacial acetic acid, from which it separates in yellow, hexagonal plates which decompose at about 274° .

Calculated for $C_{12}H_{11}ON_3S$: N, 17.1. Found: N, 17.0.

2-Ethylmercapto-4-diethoxymethyl-5-methyl-6-oxypyrimidine (XXV).—1.9 gm. of sodium were first dissolved in 250 cc. of absolute alcohol, 20 gm. of the acetal of 2-thio-4-thymine aldehyde dissolved in the resulting solution, and 15 gm. of ethyl bromide finally added. The flask was connected to a reflux condenser and heated on the water bath until the reaction mixture became neutral to litmus. The sodium bromide was then filtered off and the alcohol solution concentrated to a volume of about 25 cc. Water was then added when a colorless oil was precipitated which assumed a crystalline form when stirred. This product was filtered off and dried over sulfuric acid. The yield of pure substance was 22 gm., or practically theoretical. This compound is very soluble in alcohol and glacial acetic acid, and sparingly soluble in water. It was crystallized from 50 per cent alcohol from which

it separated in long needles. The melting point of the pure product is 100° .

Calculated for $C_{12}H_{11}O_2N_2S$: N, 10.2. Found: N, 10.2.

2-Ethylmercapto-5-methyl-6-oxypyrimidine-4-aldehyde (XXVI).—This aldehyde was formed quantitatively from the corresponding acetal by dissolving the acetal in 50 per cent acetic acid and then evaporating the solution on a water bath. The compound is white in color, slightly soluble in hot water, and easily soluble in alcohol and acetic acid. It was purified by crystallization from alcohol and separated in long needles which melted at 186° to an oil.

This aldehyde does not reduce Fehling's solution and reduces an ammoniacal silver nitrate solution only on prolonged boiling.

Calculated for $C_{12}H_{11}N_2O_2S$: N, 14.1. Found: N, 14.0.

Derivatives of 2-Ethylmercapto-5-methyl-6-oxypyrimidine-4-aldehyde. Phenylhydrazone.—A small amount of the aldehyde was dissolved in dilute acetic acid and a few drops of phenylhydrazine were added to the hot solution. There was an immediate precipitation of a yellow crystalline hydrazone, which was purified by crystallization from alcohol. It softens at 201° , remaining in a semi-melted condition to 238° at which temperature it decomposes. The crystals are needles and show a tendency to aggregate in rosettes. This hydrazone is sparingly soluble in water but soluble in glacial acetic acid.

Oxime.—The procedure followed was identical to that described before for the formation of the oxime of 2-thiothymine aldehyde. The yield was 1 gm. The product was purified by crystallization from 60 per cent acetic acid and separated in the form of distorted, elongated, prisms which decomposed at about 235° . The compound is colorless, insoluble in alcohol and water, and very soluble in glacial acetic acid.

Calculated for $C_{12}H_{11}O_2N_2S$: N, 19.2. Found: N, 18.9.

Anil.—It was found impossible to prepare a Schiff base by heating this mercapto aldehyde with pure aniline or with aniline diluted with alcohol, the mercapto group being removed and ethylmercaptan liberated in both cases.

2,6-Dioxy-5-methylpyrimidine-4-aldehyde (XXVIII).—A practically quantitative yield of this pyrimidine was obtained by the hydrolysis of the acetal of 2-ethylmercapto-4-thymine aldehyde with hydrochloric acid. 15 gm. of the acetal were dissolved in about 300 cc. of hydrochloric acid (1:1) and the solution heated on a water bath. Acid was added at intervals to replace that lost by evaporation and the heating continued until the odor of mercaptan was no longer noticed. The time required was about 48 hours. The solution was then evaporated to dryness, the residue being a white amorphous powder melting at 205°. It was purified by crystallization from dilute hydrochloric acid and separated, after standing some time, in the form of colorless distorted prismatic needles, arranged in rosettes. This compound was also observed to crystallize in hexagonal plates, from dilute hydrochloric acid.

Calculated for $C_6H_6O_2N_2 \cdot H_2O$: N, 16.3. Found: N, 16.1.

The water was removed by heating for 1 hour at 110°.

Calculated for $C_6H_6O_2N_2 \cdot H_2O$: H_2O , 10.5. Found: H_2O , 10.1.

When crystallized from absolute alcohol this aldehyde separated with one molecule of alcohol of crystallization. This alcohol was removed by heating for 1 hour at 110°.

Calculated for $C_6H_6O_2N_2 \cdot C_2H_5OH$: C_2H_5OH , 23.0. Found: C_2H_5OH , 22.9.

This aldehyde reduced Fehling's solution and an ammoniacal silver nitrate solution. It is soluble in glacial acetic acid and water. The melting point is 212–213°.

Derivatives of Thymine Aldehyde. Phenylhydrazone.—A small amount of the aldehyde was dissolved in dilute acetic acid and the solution warmed. A few drops of phenylhydrazine were then added when this hydrazone separated at once in the form of yellow needles, often arranged in rosettes. The compound decomposes at about 272° without melting. It is slightly soluble in alcohol and water and soluble in glacial acetic acid.

Oxime.—In order to prepare this oxime the following proportions were used. 1 gm. of thymine aldehyde, 0.4 gm. of hydroxylamine hydrochloride, and 0.6 gm. of sodium hydroxide. The

procedure followed was the same as that described in the preparation of the oximes already spoken of and the yield was 1 gm. The product crystallizes from glacial acetic acid in elongated four-sided plates which decompose at about 257°. The compound is difficultly soluble in acetic acid and insoluble in alcohol and water.

Calculated for $C_8H_7O_3N_3$: N, 24.8. Found: N, 24.6.

Anil.—This Schiff base was prepared by dissolving a small amount of thymine aldehyde in aniline and boiling the resulting solution for a few minutes. On cooling, the anil separated from the aniline in the form of long yellow needles which were purified by recrystallization from glacial acetic acid. The compound softened at 265° and decomposed at 272°. This anil is insoluble in water and alcohol.

Calculated for $C_{12}H_{11}O_2N_3$: N, 18.2. Found: N, 18.2.

CEREBRONIC ACID.*

V. RELATION OF CEREBRONIC AND LIGNOCERIC ACIDS.

By P. A. LEVENE AND C. J. WEST.

(From the Laboratories of The Rockefeller Institute for Medical Research.)

(Received for publication, June 16, 1916.)

In a recent publication from Thierfelder's laboratory Brigl¹ reported the results of some synthetic experiments which were initiated with the object of proving the Thierfelder-Brigl assumption of the structure of cerebronic acid. The article also contains critical remarks on our work on the same subject.

The starting point for the synthetic work of Brigl is the assumption that cerebronic acid has the structure of normal α -hydroxypentacosanic acid,

In order to prove this contention he attempted to convert cerebronic acid into the corresponding hydrocarbon, and to prove the identity of this product with the synthetic *n*-pentacosan. Secondly, it was his intention to prepare synthetically the normal α -hydroxypentacosanic acid and to prove the identity of this synthetic product with *r*-cerebronic acid.

By a rather interesting process Brigl prepared *n*-pentacosan, but did not convert cerebronic acid into the paraffin. Hence he failed to accomplish the part of the task that rested on the study of the two paraffins.

Also by a very difficult and circuitous method he prepared normal α -hydroxypentacosanic acid. The comparison of the melting points of the synthetic acid with the *r*-cerebronic acid did not lead to a convincing conclusion.

* Levene, P. A., and Jacobs, W. A., *J. Biol. Chem.*, 1912, xii, 381. Levene, P. A., and West, C. J., *J. Biol. Chem.*, 1913, xiv, 257; 1913, xv, 193; 1914, xviii, 477.

¹ Brigl, P., *Z. physiol. Chem.*, 1915, xcv, 161.

In a word, the synthetic products obtained by Brigl are interesting by themselves, but in the hands of Brigl they were of no service for the purpose of proving the structure of cerebronic acid.

The critical remarks on our work on cerebronic acid are directed not against the conclusions but against the method employed by us for the conversion of α -hydroxy fatty acids into the corresponding hydrocarbons. Thierfelder and Brigl discuss only the results of the publications of Levene and Jacobs of 1912 and of Levene and West of 1913. There the view was expressed that cerebronic acid had the structure of normal α -hydroxypentacosanic acid. The view was based on the fact that the hydrocarbon obtained from cerebronic acid melted at 53.5–54°C. This melting point was the one accepted by Marie² for *n*-pentacosan. Furthermore, cerebronic acid was converted into lignoceric acid which yielded a hydrocarbon melting at 51°C. This is the melting point accepted by Krafft³ for *n*-tetracosan.

The hydrocarbon was obtained by the action of hydriodic acid in a sealed tube at 125°C. As already stated, Thierfelder and Brigl take exception to this method. Our own work, subsequent to the first two publications, convinced us that the method was better than the conclusions. The original view on the structure of cerebronic acid, as expressed by Levene and Jacobs and by Levene and West, was subsequently modified.

The present writers regard cerebronic acid to be the α -hydroxy derivative of the next higher homologue of lignoceric acid. Naturally we cannot accept the conclusions of Thierfelder and Brigl. However, we did not have absolute confidence in the hydriodic acid process for the conversion of fatty acids into paraffins. In fact, the original object of the hydriodic acid experiment was to convert cerebronic acid into pentacosanic acid. At the same time the work of Meyer, Brod, and Soyka⁴ advanced the view that lignoceric acid had the structure of a branched chain tetracosanic acid. Since cerebronic acid is easily converted into lignoceric acid all the conclusions reached regarding the structure of one apply also to the other.

² Marie, T., *Ann. chim. phys.*, 1896, vii, 212; *Bull. Soc. chim.*, 1896, xv, 567.

³ Krafft, F., *Ber. chem. Ges.*, 1882, xv, 1711.

⁴ Meyer, H., Brod, L., and Soyka, W., *Monatschr. Chem.*, 1913, xxxiv, 1113.

We also realized the need of a revision of the melting points of the higher hydrocarbons and have adapted a process of preparation of the hydrocarbons which consisted of the following steps:

Every step of the process involved only very mild treatment. In this manner *n*-tetracosan and the isotetracosan corresponding to lignoceric acid were prepared.⁵ The first had the melting point of 54°C. (given in literature 51.1°C.) and the second 51°C., identical with that previously obtained by the hydriodic acid process.

Furthermore, we prepared *n*-tetracosanic acid⁶ and found for it a melting point of 87.5–88.0°C. (85.5–86.0°C. was given by Meyer, Brod, and Soyka). The melting point for lignoceric acid is 81°C.

Hence the structure of cerebronic acid seems to be fairly well correlated with that of lignoceric acid. For greater rigor of the proof we plan to convert lignoceric acid into an α -hydroxypentacosanic acid, which should be identical with cerebronic, and finally to compare the pentacosans obtained from cerebronic acid and the synthetic pentacosanic acid. We also contemplate converting lignoceric acid into isotricosanic acid, and by the malonic ester synthesis to arrive at pentacosanic acid which will serve both for preparation of the paraffin and of the α -hydroxy acid.

Another point of criticism is directed by Brigl against the assumption made by us for the explanation of the variability of the melting point of various samples and of various fractions of the α -hydroxypentacosanic acid obtained on hydrolysis of cerebrin. Our assumption was that the so called cerebronic acid is a mixture of optical isomers; Brigl holds the view that the isomerism of the two acids is structural. The objection of Brigl is based on the fact, first, that the difference in the melting of the optically active and inactive acids is in the neighborhood of 20°C., and second, on the fact that the synthetic normal hydroxypentacosanic acid melts 20° above the optically inactive natural acid.

The second proof of Brigl falls by itself since it has been proven that cerebronic acid does not belong to the series of normal acids.

⁵ Levene and West, *J. Biol. Chem.*, 1914, xvii, 477.

⁶ Levene, P. A., West, C. J., Allen, C. H., and van der Scheer, J., *J. Biol. Chem.*, 1915, xxiii, 71.

As to the first point of objection, it must be emphasized that we have not claimed to have established the correct melting point of either the active or the *dl*-forms of cerebronic acid. One always realizes the difficulty of any deductions from observations on mixtures of fatty acid. Our principal argument was that, regardless of the great difference in the melting points of different samples of the natural hydroxypentacosanic acids (generally mixtures), they all yield on oxidation a tetracosanic acid of the same sharp melting point of 81°C ., an acid having all other properties of lignoceric acid. It is hard to believe that two isomeric tetracosanic acids have the same melting point when the α -hydroxy derivatives of their next higher homologues differ in their melting point by more than 20°C .

The view may be further substantiated by the fact that the same sample of cerebrin yields a cerebronic acid of different melting point and of different optical power depending upon the conditions of hydrolysis. A similar observation was made by Rosenheim.⁷

However, in our previous work no detailed record was kept of the rotatory power and of the melting points of the different samples of cerebronic acids which served for oxidation into lignoceric acid. In order to add validity to our earlier evidence we prepared several samples of cerebronic acid.

The first had a melting point of $99-100^{\circ}$, $[\alpha]_D^{25} = +2.6^{\circ}$; the second, 86° , $[\alpha]_D^{25} = +1.5^{\circ}$; and the third, $91-93^{\circ}$, $[\alpha]_D^{25} = +3.55^{\circ}$.

The first two of these samples were oxidized with permanganate solution, and both yielded a tetracosanic acid melting sharply at 81°C .

Hence we feel that for the present there is not sufficient ground for a revision of the original view as to the difference in the melting points of the various cerebronic acids.

EXPERIMENTAL.

The cerebroside employed for the preparation of the cerebronic acid had a specific rotation of $[\alpha]_D^{25} = +10^{\circ}$, and in solubility and other properties corresponded to Thierfelder's cerebrin or Thudichum's phrenosin. The physical property of the fatty acid ob-

⁷ Rosenheim, O., *Biochem. J.*, 1916, x, 148.

tained from the same material differed, depending on the conditions of hydrolysis.

I. Hydrolysis with Sulfuric Acid in an Autoclave.—100 gm. of cerebrin were heated with 1 liter of 3 per cent sulfuric acid (by weight) for 24 hours in an autoclave at 110–115°. The mixture of cerebronic acid and sphingosine was filtered off, the acid extracted with acetone, and purified through the sodium and lithium salts. This free acid was then recrystallized from acetone and melted at 80–85°. The rotation of the material varied from +1.2° to +1.5°.

By repeatedly fractionating the acid with lithium acetate in methyl alcoholic solution, using the insoluble fraction each time, a sample of acid was finally obtained which melted at 99–100° and had a specific rotation of 2.69°.

$$[\alpha]_D^{25} = \frac{3.3624 \times 0.16^\circ}{0.2002 \times 1.0} = 2.69^\circ$$

0.1008 gm. substance gave 0.2796 gm. CO₂ and 0.1160 gm. H₂O.

	Calculated for C ₂₇ H ₄₆ O ₈	Found:
C.....	75.33	75.32
H.....	12.65	12.88

This material was oxidized with alkaline potassium permanganate according to Levene and Jacobs and also with permanganate in acetone solution according to Levene and West. Recrystallized from acetone, analytically pure lignoceric acid, melting at 81°, was obtained.

0.1006 gm. substance gave 0.2886 gm. CO₂ and 0.1202 gm. H₂O.

	Calculated for C ₂₇ H ₄₆ O ₈	Found:
C.....	78.20	78.22
H.....	13.20	13.37

II. Hydrolysis with 20 Per Cent Hydrochloric Acid.—Cerebrin was heated with four parts of 20 per cent hydrochloric acid and one part of 95 per cent alcohol for 48 hours, as in the preparation of sphingine.⁸ From the reaction product a cerebronic acid was isolated, which melted at 85–86°, and had a rotation of 1.5°.

⁸ Levene, P. A., *J. Biol. Chem.*, 1916, xxiv, 74.

Upon oxidation with permanganate in acetone solution, lignoceric acid was obtained, melting at 80–81°.

0.1004 gm. substance gave 0.2882 gm. CO₂ and 0.1200 gm. H₂O.

	Calculated for C ₂₁ H ₄₂ O ₄	Found:
C.....	78.20	78.27
H.....	13.20	13.34

III. Hydrolysis with Methyl Alcohol-Sulfuric Acid.—Cerebrin, having a rotation of +10°, was hydrolyzed with methyl alcohol and sulfuric acid according to the directions given in earlier articles. The product, when purified through the sodium and lithium salts, and recrystallized from acetone, melted at 88–91°. After being twice extracted with low-boiling petroleum ether, the melting point was 91–93°. The activity of this sample was

$$[\alpha]_D^{20} = \frac{0.20^\circ \times 5.857}{0.330 \times 1.0} = 3.55^\circ$$

This acid was not oxidized. The experiment is reported to show the influence of the mode of hydrolysis on the physical properties of the resulting cerebronic acid.

THE DIALYSIS OF TRYPSIN AND THE PROTEOCLASTIC ACTION OF THE PROTEIN CLEAVAGE PRODUCTS.

By CASIMIR FUNK.

(From the Harriman Research Laboratory, and the Huntington Fund, Memorial Hospital and Loomis Laboratory, New York.)

(Received for publication, June 14, 1916.)

An extensive investigation as to the nature of trypsin was undertaken and published last year by Herzfeld.¹ In this work he stated that the cleavage products of various proteins possess a distinct hydrolytic action on proteins. On the basis of his experiments he attempted to demonstrate that the active properties of pepsin are mainly due to proteoses and those of trypsin to amino-acids. In his second paper² he subjected trypsin to dialysis and found that the dialysate possessed a strong hydrolyzing effect on proteins. While it was not as active as the original ferment solution, the residue remaining in the bag was found to be practically inactive. The principal method used by Herzfeld in his experiments and by which he determined the rate of protein hydrolysis was the colorimetric or spectrophotometric comparison of the color developed by an evaporation of the solution to be examined with Ruhemann's reagent (ninhydrin) and compared with a glycine solution of known strength. There are two objections to Herzfeld's theory that the action of trypsin is due to the presence of protein cleavage products: (1) Ninhydrin was found to be only to some extent specific for amino-acids, as allantoin³ and other substances⁴ give a coloration with this reagent under certain conditions. (2) The work of Holderer,⁵ and Funk and Niemann⁶ shows that trypsin does not filter through a Chamberland filter in

⁶ Funk, C., and Niemann, A., *Z. physiol. Chem.*, 1910, lxxviii, 263.

neutral solution, and, therefore, the action of trypsin cannot be due to the presence in it of amino-acids, as under these conditions the latter would pass through the filter readily. It has been found by the author⁷ that trypsin on filtration in neutral solution is so strongly adsorbed or inactivated that even breaking the porous porcelain filter to a fine powder and extracting it with weak acid or alkali will not regenerate the power of the ferment. Recovery of the ferment would be expected if the active part of trypsin were composed of cleavage products of proteins.

Under these circumstances it was found advisable to test Herzfeld's results by a different method than that used in his work and we decided to use Van Slyke's method for the determination of amino nitrogen, and, in some instances, also the micro Kjeldahl method as recommended by Pregl.⁸ We may mention here that the results we have obtained do not support Herzfeld's view that the action of trypsin is mainly due to the presence of amino-acids and the difference in the results obtained may be due either to the fact that a modified technique was used by us or that the intensified color obtained with ninhydrin was not due to an actual increase in amino-acids.

Dialysis of Trypsin.

Herzfeld in his experiments used commercial trypsin preparations of unspecified origin, and he states that trypsin preparations with a high nitrogen content gave the best results on dialysis. The nitrogen content was not quite so high in the trypsin preparations we used as in those of this author. Solutions of different strengths were dialyzed in collodion membranes (instead of the parchment bags of Schleicher and Schull) against distilled water, the liquid being kept covered in all cases with toluene (numerous controls have entirely excluded any bacterial action in our experiments). The method employed was as follows: The original ferment solution, the dialysate, and the residue were tested separately as to their action on freshly prepared fibrin or egg albumin, then the protein and the solution to be examined were placed in collodion bags with distilled water outside, both liquids covered with tolu-

⁷ Unpublished work.

⁸ Pregl, F., *Abderhalden's Handb. biochem. Arbeitsmethoden*, 1912, v, 1344.

ene, and incubated at 37° for 24 hours. The dialysate was then poured off, washed into a fractionation flask, and evaporated *in vacuo*. The residue was washed into a measuring flask and an aliquot part analyzed for amino nitrogen and in some cases for total nitrogen.

Experiment 1.—A 4 per cent solution of Fairchild's trypsin (11.27 per cent N) was made and 5 cc. of it were placed in a bag with 50 cc. of water outside, while another 5 cc. of the same solution were put directly into 50 cc. of water. Both beakers were incubated for 24 hours. We have used stronger solutions of the ferment than Herzfeld in order to magnify the ultimate results. After incubation the residue in the bag was again diluted to 50 cc. Amino nitrogen determinations were made on the three solutions: (1) the original ferment, (2) the dialysate, and (3) the residue.

1. Original ferment gave 0.0064 gm. NH_2 N.
2. Dialysate " 0.0051 " "
3. Residue " 0.0012 " "

From these analyses we can see that a large part of the amino-acids originally present in the ferment solution dialyzed out.

In the above experiment with Fairchild's trypsin, which, upon repetition gave the same results, we find a diminution of proteoclastic action both in the dialysate and the residue as compared with the original ferment solution. Furthermore the dialysate does not show any proteoclastic effect on the protein, but on the contrary, a diminution of amino nitrogen.

Experiment 3.—In this experiment trypsin from Armour and Company (12.19 per cent N) was used and the proteolysis was determined both by the amino nitrogen and by total nitrogen determinations using the micro Kjeldahl method. A 10 per cent solution of the ferment was employed.

1. Original ferment gave 0.026 gm. NH_2N .
2. Dialysate " 0.0145 " "

The dialysate, although very much richer in amino nitrogen than the residue, had no hydrolyzing effect on the protein, and the residue was very much more active than the dialysate. The dialysate showed a diminution of amino nitrogen and total nitrogen in the outside fluid, as in all our experiments where a dialyzing membrane was used. Herzfeld considers also a possible synthetic action of the ferment, or amino-acid. We prefer to explain this phenomenon for the present as a mere adsorption of the cleavage products by the membrane, or by the protein in the dialyzing bag.

Experiment 4.—Pancreatine from Parke, Davis and Company in 10 per cent solution was used (11.92 per cent N), the insoluble part being filtered off.

1. Original ferment gave 0.0192 gm. $\text{NH}_2 \text{ N}$.

After having found that the dialyzing portion of the trypsin had, in our experiments, no proteolytic action on proteins we repeated some of Herzfeld's experiments on the proteoclastic action of amino-acids⁹ and peptides on proteins.

Action of Protein Cleavage Products on Proteins.

Herzfeld has shown, by means of his colorimetric ninhydrin method, that amino-acids and peptides have a distinct proteolytic

⁹ We are indebted for certain of these preparations to Dr. W. G. Lyle and Dr. P. A. Levene.

action on certain proteins, the aliphatic amino-acids being more effective than the aromatic ones. In one case he performed a direct experiment, allowing glycine to act on fibrin. On evaporation of the dialysates, and drying to constant weight, he found that the residue obtained from the action of glycine on fibrin weighed more than the residues obtained in the control experiment. We repeated this experiment using the amino nitrogen determination as an index of hydrolysis, but, as glycine does not react in the usual way with nitrous acid and gives more than the theoretical amount of gas, another experiment was done for the total nitrogen estimation.

Glycine and Fibrin.

A 2 per cent solution of glycine was used, which was added directly to the fibrin in a bag.

	NH ₂ N. gm.
5 cc. glycine solution.....	0.0184
5 " " " and 0.5 gm. fibrin.....	0.01856
0.5 gm. fibrin.....	0.00018

We found no increase of amino nitrogen. In another experiment a 4.9 per cent solution of glycine was used without dialysis and the solutions covered with toluene were left in the incubator for 6 days.

	NH ₂ N. gm.	Total N. gm.
5 cc. glycine in 40 cc. water.....	0.0495	0.0356
5 " " and 0.5 gm. fibrin.....	0.0482	0.0461
0.5 gm. fibrin.....	0.00058	0.0014

In this experiment again we find no increase in amino nitrogen, but, in confirmation of Herzfeld's result, an increase in total nitrogen. This at present cannot be explained, although it was obtained by us in subsequent experiments, but not to such a marked degree as in the case of glycine.

This experiment was performed in order to test whether the dialysate possesses synthetical action. This phenomenon could not be demonstrated as the amounts calculated in the last experiment were 0.01637 NH₂ N and 0.02512 total N, which closely corresponded to our results. We have also attempted testing the synthetic action of the ferment itself, or its dialysate, by the optical method and also by direct incubation of amino-acid with the ferment. None of the experiments were successful, nor were we able to detect any hydrolyzing properties of the cleavage products in their action on proteins.

SUMMARY.

Trypsin, when subjected to dialysis in collodion bags, loses a large part of its amino nitrogen, corresponding to the passage of amino-acids into the dialysate. The dialysate was found to be without hydrolyzing effect on proteins, whereas, in most cases the residue was found to have distinct proteoclastic properties. The dialysis of trypsin was followed by a marked inactivation of the ferment. The diminution of amino nitrogen, where the dialysate was allowed to act upon protein, is perhaps due to the adsorption of a certain quantity of the cleavage products by the membrane, or by the protein substrate, and is apparently not due to synthetic action. The amino-acids and peptides used had no hydrolyzing effect on proteins, as an increase of amino nitrogen was never found. Occasionally, as in the case of glycine, an increase in total nitrogen was found, for which we can offer no explanation.

THE INFLUENCE OF ETHYL ALCOHOL AND GLYCEROL UPON THE RATE OF SOLUTION OF CASEIN BY SODIUM HYDROXIDE.

BY T. BRAILSFORD ROBERTSON AND K. MIYAKE.

(From the Rudolph Spreckels Physiological Laboratory of the University of California, Berkeley.)

(Received for publication, June 10, 1916.)

In previous articles¹ we have shown that the rate of solution of casein in an alkaline solvent is determined by the velocity with which the casein particles are penetrated and wetted by the solvent, the relationship between the time of exposure to the solvent (t) and the amount of casein dissolved (x) being expressed by the formula $x = Kt^m$, in which K and m are constants which vary with the nature of the solvent. The product $K \times m$ we have called the coefficient of penetration, and we have shown that the addition of alkali or alkaline earth chlorides to an alkaline solution employed as solvent decreases the value of the coefficient of penetration and, consequently, the rate of solution of the casein.

It appeared of special interest in this connection to study the effect upon the rate of solution of casein in alkaline solvents of organic substances which are known to exert a marked effect upon surface tension. Alcohol and glycerol are known to reduce the tension of a solid-water interface and the addition of these substances to the alkaline solvent should evidently, if the above outlined theory correctly represents the facts, retard the rate of penetration and, consequently, the rate of solution of the casein. While, as will be seen, our results are in harmony with the requirements of the theory, certain anomalies were encountered in the behavior of the solvents containing

¹ Robertson, T. B., *J. Phys. Chem.*, 1910, xiv, 377; *Arch. ges. Physiol.*, 1913, clii, 524. Robertson, T. B., and Miyake, K., *J. Biol. Chem.*, 1916, xxv, 351.

alcohol, anomalies which are attributable to the fact that alcohol is a protein coagulant, or dehydrating agent.

The casein employed in these experiments was the same as that used in our previously reported investigations and the experimental technique was also the same. As a standard alkaline solvent we employed 0.016 N sodium hydroxide containing varying concentrations of alcohol or glycerol. The volume of solvent employed was always 100 cc.; 5 gm. of casein were dropped into the solvent and the mixture was stirred at an approximately constant rate. Samples of the mixture were withdrawn from time to time, rapidly filtered, and the concentration of casein contained in the filtrate was determined by the refractometric method.

Tables I to XIV embody the results obtained with the solvents containing alcohol, and these results are also depicted graphically in Figs. 1 and 2. It will be seen that the addition of alcohol markedly decreases the rate of solution of casein by dilute sodium hydroxide. In the mixtures containing over 4 M and less than 8 M alcohol, however, a curious phenomenon is observed. It will be seen, on consulting Tables VII to XI, that in these mixtures a partial reprecipitation of the casein initially dissolved occurs, so that after 2 hours of stirring in the mixtures containing from 4.5 M to 6 M alcohol (Tables VII to X) the amount of casein in solution is actually less than it is after $\frac{1}{2}$ hour of stirring.

FIG. 1. The influence of ethyl alcohol upon the rate of solution of casein by 0.016 N sodium hydroxide.

FIG. 2. The influence of ethyl alcohol upon the rate of solution of casein by 0.016 N sodium hydroxide.

It is evident that in mixtures which contain between 4 M and 8 M alcohol the formula $x = Kt^m$ does not apply to the rate of solution of the casein, for this formula implies a continuous irreversible process, while in the presence of the above mentioned concentrations of alcohol the process of solution is evidently partially reversible.

Above and below this critical zone of concentrations the relation between the time of stirring and the concentration of casein dissolved is adequately expressed by the formula cited, as will be evident on comparing calculated and observed values of x in Tables I to VI and XII to XIV inclusive, the deviations of the calculated from the observed values rarely being greater than the possible error in the refractometric determination of x .

On investigating the effect of alcohol upon the magnitude of the coefficient of penetration (Table XV and Fig. 3) it is evi-

dent that in the zone of concentrations lying between 4 M and 8 M alcohol the character of the relationship between the concentration of alcohol and the magnitude of the coefficient of penetration is undergoing a transition. For concentrations of alcohol lying below 4.5 M the coefficient of penetration decreases with negative acceleration as the concentration of alcohol increases. In mixtures containing over 7 M alcohol, however, the coefficient of penetration decreases with positive acceleration as the concentration of alcohol increases. In mixtures containing concentrations of alcohol lying between 4.5 M and 7 M inclusive, the character of the relationship is indeterminate.

FIG. 3. The influence of ethyl alcohol upon the coefficient of penetration. The broken lines indicate the calculated continuations of the continuous lines drawn through the experimentally determined points.

Applying the interpolation equation employed in our previous article, $K_1m_1 - Km = \alpha c + \beta c^2$ where $K_1m_1 - Km$ represents the decrease in the coefficient of penetration, c represents the concentration of alcohol, and α and β are constants, we find that for concentrations of alcohol lying below 4.5 M ($K_1m_1 = 0.358$) the equation becomes:

$$0.358 - Km = +0.0495c - 0.00340c^2$$

while for concentrations lying above 8 M ($K_1m_1 = 0.185$) the equation becomes:

$$0.185 - Km = -0.00159 (c-8) + 0.00586 (c-8)^2$$

which implies that at concentrations of alcohol lying below 8.27 M the rate of solution increases with increasing concentration of alcohol.

The only explanation of these curious phenomena which offers itself lies in the fact that alcohol is a coagulant of proteins and therefore brings about dehydration and consequent polymerization of protein molecules.² At low concentrations of alcohol we have to deal with the rate of solution of "single" molecules of sodium caseinate, at higher concentrations with the rate of solution of polymerized molecules which we may, for the sake of brevity, term "double" molecules, while at intermediate concentrations we have to deal with a rate of solution which is compounded of the separate rates of solution of the two types of molecules. With increasing concentration of alcohol the rate of solution of the single molecules is progressively diminished, but that of the double molecules is increased, owing to the fact that the proportion of double to single molecules coming off from the internal surfaces of the casein particles is being increased sufficiently rapidly to more than compensate for the retardation of the total rate of solution by the alcohol. At 8 M concentration so large a proportion of the molecules coming off are of the double type that thereafter the retarding effect of increasing concentration of alcohol upon the total rate of solution (penetration) more than compensates for any further increase in the proportion of double molecules.

At intermediate concentrations we have seen that the quantity of casein dissolved at first increases and thereafter diminishes with time, casein which is initially dissolved being later reprecipitated. This can only be interpreted by supposing that the condition of the bulk of the solution outside the casein particles differs, at any rate for some portion of the time occupied in solution, from the condition of that portion of the solvent which has actually penetrated the protein particles. We know that any substance such as alcohol, which reduces the tension of a solid-water interface, tends to become concentrated at such

² Robertson, *Die physikalische Chemie der Proteine*, Dresden, 1912.

an interface.³ Hence at the surfaces of the casein particles the concentration of alcohol will be greater than in the bulk of the fluid. Suppose that the concentration of alcohol in the bulk of the fluid be such that at equilibrium the proportion of double molecules is 50 per cent. If, now, the concentration of alcohol at the surface of the casein particles be such as to lead to the formation of 60 per cent of double molecules, then out of every thirty molecules coming off from the interior surfaces of the casein particles eighteen will be of the double type and only twelve of the single type. As these come out into the bulk of the liquid, equilibrium will tend to be reestablished, resulting in the formation of sixteen double and sixteen single molecules, with an increase in the total number of molecules to thirty-two. This equilibrium may be supposed to be slowly established, and meanwhile the rate of solution of the casein has fallen very low; that is, the fall in concentration or concentration gradient from within the casein particles to the bulk of the fluid outside is very small. By this time, however, as a result of depolymerization, the molecular concentration of casein in the outer fluid has actually become greater than that in the saturated solution which fills the interior spaces of the casein particles. Thus the concentration gradient has become negative, and as the more concentrated casein solution diffuses back into the less concentrated but nevertheless saturated solution filling the interspaces of the sponge-like particles of casein, the excess of casein must be reprecipitated. When the concentration of alcohol is sufficiently great, so that the molecular condition of the casein is practically the same within and without the particles, a negative concentration gradient can never arise and the curve of solution reassumes the normal form, representing now, however, the curve of solution of double molecules instead of single molecules as at lower concentrations of alcohol.

It may here be pointed out that the observed results cannot be interpreted as the result of errors in the determination of casein due to abnormal refractivity in alcohol-water mixtures, since the refractivity of casein dissolved in alcohol-water mix-

³ Thomson, J. J., *Application of Dynamics to Physics and Chemistry*, London, 1888, 190.

tures of the proportions employed is normal.⁴ On the other hand, it has been directly shown by electrolytic transference measurements that the weight of the casein particle carrying a unit charge is progressively increased by the addition of increasing concentrations of alcohol to the solution.⁵ We are justified in concluding from the above data, therefore, that at concentrations of alcohol lying below 4.5 M casein molecules in the presence of 0.016 N NaOH are practically all of the single type, while at concentrations lying above 7.0 M they are practically all of a polymerized type. At intermediate concentrations of alcohol the proportion of polymerized to single molecules continuously increases with increasing concentration of alcohol.

This interpretation of the above facts finds further confirmation in the effect of glycerol upon the rate of solution of casein in dilute alkali. In glycerol we have a substance which, like alcohol, reduces the tension of a solid-water interface but which, unlike alcohol, does not coagulate (polymerize) proteins in solution. Accordingly we find that glycerol (Tables XVI to XX) decreases the rate of solution of casein progressively as its concentration increases. No sign of reprecipitation of dissolved casein is observed in any of the mixtures. The penetration formula $x = Kt^m$ applies to the rate of solution in all of the mixtures employed and the value of the coefficient of penetration progressively decreases in a smooth curve with decreasing acceleration as the concentration of glycerol increases (Fig. 4). For all the concentrations of glycerol employed, the relationship of the coefficient of penetration to the concentration of glycerol may be expressed by the equation:

$$K_1m_1 - Km = 0.0525 c - 0.00243 c^2.$$

FIG. 4. The influence of glycerol upon the coefficient of penetration.

SUMMARY.

1. Alcohol and glycerol, both of which reduce the tension of a solid-water interface, also retard the penetration of casein particles by 0.016 N NaOH.

2. The penetration formula $x = Kt^m$ expresses the relationship between the quantity of casein dissolved and the time of stirring in all the glycerol-water mixtures studied and in alcohol-water mixtures containing less than 4.5 M or more than 7 M alcohol. The formula does not apply to the rate of solution of casein in 0.016 N NaOH containing between 4 M and 8 M alcohol. In these mixtures the initial solution of casein is succeeded, after prolonged stirring, by partial reprecipitation.

3. In concentrations lying below 4.5 M the coefficient of penetration decreases with negative acceleration as the concentration of alcohol increases. In concentrations lying above 7 M the coefficient of penetration decreases with positive acceleration as the concentration of alcohol increases. In mixtures containing concentrations of alcohol lying between 4.5 M and 7 M, inclusive, the character of the relationship of the magnitude of the coefficient of penetration to the concentration of alcohol is indeterminate.

4. It is inferred that in concentrations of alcohol lying below 4.5 M casein molecules in the presence of 0.016 N NaOH are practically all of the single type, while at concentrations lying above 7.0 M they are practically all of a polymerized type. In intermediate concentrations of alcohol the proportion of the polymerized to the single molecules progressively increases with increasing concentration of alcohol.

CHONDROSAMINE.

By P. A. LEVENE.

(From the Laboratories of The Rockefeller Institute for Medical Research.)

(Received for publication, July 5, 1916.)

By the previous work of Levene and La Forge¹ there were established a number of facts concerning chondrosamine. One of the principal ones was that on oxidation with nitric acid chondrosaminic acid was transformed into an inactive anhydrotetrahydroxyadipic acid. This fact alone suffices to limit the possible configurations of chondrosamine to that of a lyxohexosamine or of a ribohexosamine. Two other facts swung the weight of the argument in favor of the second hypothesis. They were, first, the similarity of the osazones obtained from altrose and from chondrosamine. The similarity was found in their melting points and in their optical activity. The other fact was that two hexosaminic acids, lyxohexosaminic and chondrosaminic, very different in their physical properties, led to formation of inactive anhydrotetrahydroxyadipic acids. Accepting that all hexosaminic acids showed the same behavior in the sense of Walden's inversion, one was forced to the conclusion that chondrosamine is not a lyxohexosamine, and hence is a ribosimine. The conclusion seemed perfectly logical. Subsequent development of the work has caused some doubt in the correctness of the conclusion.

Chronologically our faith in the correctness of this assumption was shaken first by the observations on the optical rotation of the two anhydropentoxycaproic acids obtained from chondrosamine. On the assumption that chondrosamine is a ribohexosamine it must also be assumed that it belongs to the *l* series. Were this true, one was to expect that the anhydropentoxycaproic acid (I) which leads to the inactive anhydrotetrahydroxyadipic acid is to have a lower dextrorotation or a higher levorotation

¹ Levene, P. A., and La Forge, F. B., *J. Biol. Chem.*, 1914, xviii, 123; 1915, xx, 433; xxii, 331.

than the acid (II) yielding the optically active adipic acid. This is seen from the following:

In reality when the brucine salts of the two acids were prepared it was found that the salt of the acid assumed to have the configuration (I) had a lower levorotation than that of (II).

In view of this discrepancy it was decided to reinvestigate the hexosazone obtained from chondrosamine. It was prepared in the same manner as originally, but was recrystallized out of boiling water containing enough pyridine to complete solution. Two recrystallizations sufficed to yield a perfectly pure product which under the microscope consisted of very elongated thin plates with pointed ends and macroscopically had the appearance of bright, glistening scales. This product was suspended in a little alcohol (99.5 per cent) and ether, allowed to stand about 1 hour, and filtered. The dry osazone melted at 201°C. and decomposed at 202°C. Mixed with the osazone obtained from either galactose or from galactosamine, it showed no depression of melting point. Furthermore, pure altrosazone, previously analyzed, which kept its bright lemon yellow color for 1 year without change, was recrystallized out of water and pyridine and then transferred into a mixture of ether and alcohol. It immediately dissolved and on standing, crystallized in long, very fine needles. The melting and decomposition point remained unchanged, 178° and 189°C. respectively. Also the character of mutarotation of osazone of chondrosamine was the same as that of galactosazone. Hence there was no doubt that chondrosamine yielded galactosazone.

We then turned to the two inactive anhydrotetrahydroxy-

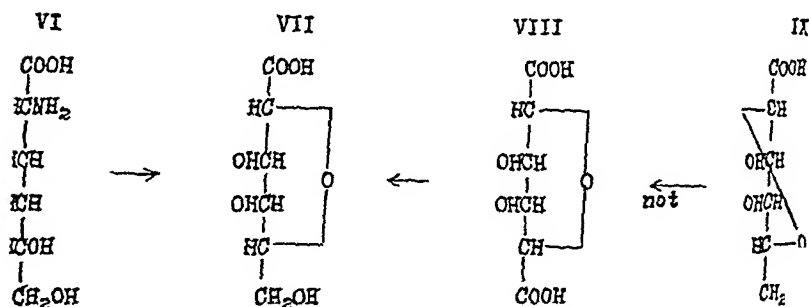

dipic acids. Originally it was found that they differed in their melting points by about 2° . The one obtained from chondrosamine was very slightly colored. It is now recrystallized once more out of acetone. Parallel melting points were made of this substance and a mixture of this and of the anhydromucic acid (obtained from lyxohexosaminic acid) had the identical melting point between 202° and 203°C . (corrected).

It seems on the basis of the present evidence that chondrosamine has the configuration of one of the lyxohexosamines. Fortunately it was possible to prepare a lyxohexosamine synthetically from lyxohexosaminic acid. This sugar in its physical properties was distinctly different from chondrosamine. Hence there is here an instance of two different sugars yielding the same osazone, and two different α -hexosaminic acids yielding the same anhydromucic acid. The facts are explained easily on the assumption that the two pairs of substances are epimeres; that is, that one sugar has the configuration of galactosamine and the other of talosamine, and that the two α -hexosaminic acids have the corresponding configuration. Hence one could assume that in the process of formation of anhydromucic acid one of the hexosaminic acids undergoes a Walden inversion while the other keeps its original configuration. This is seen from the following:

In reality, however, the phenomenon cannot be dismissed by this assumption, and for the following reason. If lyxohexosaminic acid on desamination and subsequent oxidation with nitric acid leads to anhydromucic, then on desamination without

oxidation one should expect the formation of anhydrogalactonic acid. However, when it was attempted to obtain this acid in form of a brucine salt, a substance was obtained which seemed identical with the brucine salt obtained from chondrosamine by desamination and by subsequent oxidation with bromine. This experience seemed puzzling, since it is hard to conceive of a change in configuration brought about by the nitric acid oxidation.

The fact is that starting with the same lyxohexosaminic acid one obtains on one hand anhydromucic acid (VIII), on the other anhydrotalonic (IX) which cannot be converted into (VIII). Of course there is the possibility that on desamination of lyxohexosaminic acid both (VII) and (IX) are formed. On further oxidation with nitric acid there is a possibility that substance (IX) is destroyed, hence only (VIII) is formed. On the other hand, from a mixture of the two monocarboxylic acids (VII) and (IX) the form (IX) is isolated more readily than the epimere.

The phenomenon surely needs further investigation. However, the fact that chondrosamine on desamination leads to a monocarboxylic acid identical with one obtainable for lyxohexosaminic acid makes untenable an assumption of the configuration of chondrosamine as that of ribohexosamine, since the anhydrohexonic acids obtainable from the latter are different from forms (VII) and (IX); this is seen from (X) and (XI):

For the further study of the configuration of chondrosamine, as in the case of glucosamine, it seemed to us necessary to prepare the chondrosaminoheptonic acid. The theoretical reasons were given in the note on glucosaminoheptonic acid. Great difficulties were encountered in crystallizing the chondrosaminoheptonic acid. However, after many failures the chondrosaminoheptonic acid was obtained in the form of large elongated macroscopic prisms with pointed ends.

Finally it was found desirable to simplify the method of preparation of chondrosamine, so as to render the material more accessible and less costly.

EXPERIMENTAL PART.

Preparation of Chondrosamine.—Nasal septums, freed from bone and adhering tissue, were passed through a meat chopper. About 20 pounds of this material were suspended in 30 liters of a hot 2 per cent solution of potassium hydrate. In course of 2 days nearly all the cartilage was dissolved. The solution was then rendered slightly acid by means of acetic acid and neutralized by an excess of barium carbonate. It was concentrated to about one-third of the original volume by immersing into it a steam coil. When sufficiently concentrated, and when most of the protein material was coagulated, the mixture was filtered on suction funnel provided with a layer of kieselguhr. To the solution basic lead acetate was added as long as a precipitate formed. The lead salt was washed by decantation (about ten times), and then filtered over suction. The substance in this

state contained about 75 per cent of water. Portions of the salt of about 2 kilos each were taken up in precipitating jars and a minimum amount of glacial acetic acid was added so as to bring about a solution of the lead salt. The process was facilitated by continuous stirring with a mechanical stirrer. When solution was completed an excess of glacial acetic acid was added until precipitation of the chondroitin sulfuric acid was completed. The precipitate was then filtered, once more treated with glacial acetic acid, again filtered, and then suspended in 95 per cent alcohol. This operation was once repeated. The product was finally filtered and dried on water bath. The process required only 3 liters of glacial acetic acid. 400 gm. of the dry substance were taken up in 1,600 cc. of a 20 per cent solution of hydrochloric acid, 40.0 gm. of stannous chloride and 100.0 gm. of barium chloride added, and all was heated with return condenser over a free flame for 12 hours. When the hydrolysis was completed the reaction product was filtered. The filtrate was concentrated under diminished pressure to a thick syrup. This was taken up in 800 cc. of water and the barium removed by means of sulfuric acid. The final filtrate was concentrated under diminished pressure to a thick syrup. This was taken up in about 100.0 cc. of methyl alcohol, and ether was added very cautiously until the sugar began to crystallize. The crystallization progressed continually for about 24 hours. The yield was about 35-40.0 gm. of chondrosamine chlorhydride.

Chondronic (Anhydrotalonic) Acid. Experiment I.—15.0 gm. chondrosamine hydrochloride were taken up in 75.0 cc. of water, 15 gm. of silver nitrite added, the solution being kept in ice alcohol mixture at the beginning of the reaction, and then allowed to stand over night. The following morning the excess of silver was removed by means of hydrogen sulfide, then 35.0 gm. of bromine were added, and the mixture was allowed to stand 40 hours. The solution was concentrated under diminished pressure to remove bromine, the hydrobromic acid was removed by lead carbonate and silver carbonate, and the excess of silver by means of hydrogen sulfide. The solution was then boiled with brucine. On cooling, the excess of brucine was removed by filtration. The filtrate was concentrated to a syrup and allowed to crystallize. The precipitate was filtered, washed with alcohol, dissolved in

a minimum amount of hot water, and alcohol (99.5 per cent) was added until crystallization began.

In this stage the substance had practically the same rotation as found previously by Levene and La Forge;² namely,

$$[\alpha]_D^{20} = \frac{-1.28^\circ \times 2.5876}{1 \times 0.2016 \times 1.03} = -15.94^\circ$$

(the sign + in the earlier paper is a typographical error).

After repeated fractionation from alcohol the rotation was reduced to the following:

$$[\alpha]_D^{20} = \frac{-0.32^\circ \times 2.0329}{1.0 \times 0.0521} = -12.45^\circ$$

The substance had the following composition.

0.0970 gm. substance dried in a vacuum desiccator over sulfuric acid at the temperature of water vapor gave 0.2154 gm. CO₂ and 0.0558 gm. H₂O.

	Calculated for C ₂₂ H ₃₅ N ₅ O ₁₀	Found:
C	60.81	60.56
H ...	6.34	6.43

Experiment II.—It was found advisable to remove the nitric acid in all those experiments where either nitric or nitrous acid were used in the process of preparation of a substance. This procedure facilitated crystallization of the desired substance and improved the yield. The nitric acid was reduced by zinc dust in a sulfuric acid solution, continuing the reaction as long as a test of the solution still showed the presence of nitric acid (brucine test). This operation was introduced as a routine in the preparation of the mono- and dicarboxylic sugar acids.

10.0 gm. of chondrosamine hydrochloride were taken up in 75.0 cc. of water, a few drops of hydrochloric acid added, and 10.0 gm. of silver nitrate were added in small portions. The reaction mixture was agitated by a mechanical stirrer, and the reaction vessel was kept immersed in a cooling mixture. After addition of all the silver the material was allowed to stand overnight. The following morning the solution still contained 0.150 gm. of amino nitrogen; hence 2.0 gm. of silver nitrite and 2.0

² Levene and La Forge, *J. Biol. Chem.*, 1914, xviii, 130.

cc. of hydrochloric acid (sp. gr. 1.19) were added and the mixture was allowed to stand 2 hours. The filtrate was freed from silver, the volume brought to 100.0 cc., and 25.0 gm. of bromine were added. The bromine was allowed to act for 60 hours with occasional shaking. The solution was then concentrated to half of the original volume and reduced with zinc and sulfuric acid. Finally it was freed from zinc and from mineral acids and converted into the brucine salt of chondronic acid. The excess of brucine was removed by means of chloroform. The aqueous solution was concentrated nearly to dryness. On cooling, it turned into a solid mass. This was recrystallized three times out of 99.5 per cent alcohol. The substance crystallized in form of heavy short prisms (there were among them many typical octahedrons) and melted at 218°C. (corrected), and decomposed at 223°C.

Its optical rotation was as follows:

$$[\alpha]_D^{20} \approx \frac{-0.34^\circ \times 2.0130}{1.0 \times 0.0550} = -12.4^\circ$$

The substance, dried to constant weight under diminished pressure at the temperature of water vapor, had the following composition.

0.0990 gm. substance gave 0.2210 gm. CO₂ and 0.0590 gm. H₂O.

	Calculated for C ₂₃ H ₂₃ N ₂ O ₁₀	Found:
C.....	60.61	60.68
H.....	6.34	6.66

Epichondronic (Anhydrogalactonic?) Acid.—10.0 gm. of chondrosaminic acid were taken up in 80.0 cc. of water. 8.0 gm. of silver nitrite and 20.0 cc. of 10 per cent hydrochloric acid were added. The mixture was allowed to stand over night. In course of the next day two portions of 4.0 gm. of silver nitrite and of 10 cc. of 10 per cent hydrochloric acid were added. By the end of the day desamination was complete. The silver was removed by means of hydrogen sulfide, and the filtrate from the sulfide reduced by means of zinc and sulfuric acid. The final solution was boiled $\frac{1}{2}$ hour with excess of brucine. The excess was removed by means of chloroform. The brucine salt was finally

purified by recrystallization out of 99.5 per cent alcohol. The substance crystallized in form of long heavy prisms and melted at 244°C. (corrected).

The substance had the following rotation:

$$[\alpha]_D^{20} = \frac{-0.23 \times 2.0304}{1.0 \times 0.0506} = -9.23^\circ$$

The dried substance had the following composition.

0.1004 gm. substance gave 0.2246 gm. CO₂ and 0.0397 gm. H₂O.

	Calculated for C ₂₂ H ₃₂ N ₂ O ₁₀ :	Found:
C.....	60.61	61.00
H.....	6.34	6.65

Desaminized Lyxohexosaminic Acid.—10.0 gm. of lyxohexosaminic acid were desaminized following the same procedure as with chondrosaminic acid. The brucine salt did not change its melting point, nor rotation, during the last two recrystallizations. The total number of recrystallizations out of 99.5 per cent alcohol was five. Microscopically the crystals were undistinguishable from those of the brucine salt of chondronic acid. The melting and decomposition points were the same respectively, 218° and 223°C. A mixed melting point of the two substances taken at the same time was identical with that of the individual substances.

The substance had the following rotation:

$$[\alpha]_D^{25} = \frac{-0.30^\circ \times 1.9926}{1.0 \times 0.0500} = -11.96^\circ$$

The substance had the following composition:

0.1040 gm. substance, dried in a vacuum drying apparatus at the temperature of water vapor, gave 0.2219 gm. CO₂ and 0.0575 gm. H₂O.

	Calculated for C ₂₂ H ₃₂ N ₂ O ₁₀ :	Found:
C.....	60.61	60.27
H.....	6.34	6.41

Osazone of Chondrosamine.—4.0 gm. of chondrosamine hydrochloride were dissolved in 400.0 cc. of water, and enough sodium acetate was added to neutralize the hydrochloric acid. To this

solution were added 10.0 gm. of phenylhydrazine dissolved in glacial acetic acid. The solution was then immersed for 5 hours into a boiling water bath. A considerable precipitate of osazone appeared during the process of heating. A voluminous precipitate formed on cooling over night. The precipitate was then filtered, washed, and suspended in 500 cc. of hot water. The flask was placed over a flame and pyridine added in small portions until osazone dissolved. The operation was repeated once. Under the microscope the osazone consisted of long plates with pointed ends. No impurity could be noticed on the microscopic slide. The precipitate was filtered on a suction funnel, washed with a very small portion of alcohol, and then transferred into a solution of equal parts of alcohol and ether, allowed to stand for several hours in refrigerator, and filtered. It had the appearance of very light orange glistening plates. It melted at 201° and decomposed at 202°C . A mixed melting point with galactosazone was identical with the original. Also a mixed melting point with the osazone obtained from synthetic lyxohexosamine was identical.

For the optical rotation only 0.050 gm. were used, since it was found that by employing 0.100 gm. in the Neuberg pyridine-alcohol solution one was not certain of accomplishing rapidly a complete solution. A parallel experiment was made with the osazone obtained from the synthetic lyxohexosamine.

The initial rotation in a 0.5 dm. tube was $\alpha = +0.36^{\circ}$									
After 24 hours	"	"	"	"	"	"	"	"	$= 0.00^{\circ}$
" 40	"	"	"	"	"	"	"	"	$= -0.10^{\circ}$
" 80	"	"	"	"	"	"	"	"	$= -0.25^{\circ}$
" 96	"	"	"	"	"	"	"	"	$= -0.30^{\circ}$

Observations were interrupted at this point.

Chondrosaminoheptonic Acid.—38.0 gm. of chondrosamine hydrochloride were taken up in 30.0 cc. of water, 12.0 cc. of 80 per cent prussic acid were added, and the hydrochloric acid was neutralized by means of 17.0 cc. of strong ammonia. The flask was allowed to stand from 5 to 7 days. The reaction product was taken up in 1 liter of water and concentrated under diminished pressure to a thick syrup. The residue was again taken up in water and again concentrated. This operation was repeated four times. Finally it was treated with a solution of

basic lead acetate and with baryta water as long as a precipitate formed. This was washed by decantation ten times, then it was filtered, suspended in water, and decomposed by means of hydrogen sulfide. The filtrate from the sulfide was concentrated to about 400 cc. and then boiled with copper carbonate. The solution of the copper salts, perfectly blue in color, was concentrated to a thick syrup. At this stage the copper salt was precipitated by means of alcohol in pure form, though still amorphous.

0.1034 gm. substance, on combustion on a modified Dennstedt furnace, gave 0.1114 gm. CO_2 , 0.0392 gm. H_2O , and 0.0290 gm. CuO .

	Calculated for $\text{C}_7\text{H}_{13}\text{NO}_2\text{Cu}$:	Found:
C.....	29.30	29.38
H.....	4.57	4.24
Cu.....	22.17	22.77

However, the substance, although obtained in identical manner, did not always give the same good agreement with the theory.

The copper salts obtained from five experiments were dissolved in water, freed from copper, and the solution was concentrated under diminished pressure to a syrup. This was gradually transferred into 99.5 per cent alcohol which was kept agitated by means of a mechanical stirrer. A white powder formed, which after washing with alcohol and ether and drying was no longer hygroscopic. The precipitate was suspended in 750 cc. of alcohol (99.5 per cent) and hydrochloric acid gas was passed in, in a lively stream. Part of the acid dissolved. The greatest part, however, remained insoluble. After some time a flocculent precipitate of the ester appeared, which again disappeared, and a second permanent precipitate of the lactone settled out.

The reaction product was allowed to stand over night. The following day the supernatant liquid and the flocculent precipitate of the lactone could be easily removed. The remaining alcohol-insoluble part was dissolved in water and the hydrochloric acid was removed by means of lead carbonate and silver carbonate. The final solution was concentrated to about 100.0 cc. and methyl alcohol was added in very small portions until there appeared a permanent opalescence. On standing over night an oil settled out. The supernatant liquid was decanted, and

each fraction allowed to stand separately. After 3 days' standing in the supernatant liquid fraction there appeared a rosette composed of prisms with needle-shaped points. The crystals were about 3 mm. long. From that moment crystallization proceeded rapidly. The yield was 5.0 gm. Soon also the oil began to crystallize and in course of a day solidified to a crystalline mass. It was filtered, dissolved in little water, and methyl alcohol was added in small portions until the acid began to crystallize. The yield was 4.0 gm. The original crystal form did not change on recrystallization. The air dry acid lost approximately one molecule of water on drying in a vacuum drying apparatus at the temperature of chloroform vapor. When heated at a higher temperature it continued losing weight indefinitely, at the same time changing color. The substance melted at 136° C. (corrected) and had the following composition.

0.1006 gm. air dried substance gave 0.1292 gm. CO_2 and 0.0639 gm. H_2O .

0.1500 gm. substance employed for Kjeldahl nitrogen estimation required for neutralization 6.00 cc. 0.1 N acid.

	Calculated for $\text{C}_7\text{H}_{11}\text{NO}_7 + \text{H}_2\text{O}$:	Found:
C.....	34.59	34.82
H.....	7.00	7.11
N.....	5.76	5.60

The substance had the following optical rotation in 2.5 per cent hydrochloric acid.

$$[\alpha]_D^{20} = \frac{\text{Initial.}}{1.0 \times 0.0516} = -11.95^{\circ} \quad [\alpha]_D^{20} = \frac{\text{Equilibrium.}}{1.0 \times 0.0516} = -14.40^{\circ}$$

$$[\alpha]_D^{20} = \frac{-0.29^{\circ} \times 2.1265}{1.0 \times 0.0516} = -11.95^{\circ} \quad [\alpha]_D^{20} = \frac{-0.35^{\circ} \times 2.1265}{1.0 \times 0.0516} = -14.40^{\circ}$$

THE SYNTHESIS OF HEXOSAMINES. I.

By P. A. LEVENE.

(From the Laboratories of The Rockefeller Institute for Medical Research.)

(Received for publication, July 5, 1916.)

The need of the synthesis of hexosamines became very evident after the discovery of the new sugar chondrosamine. The explanation of its structure was facilitated by the synthesis of one lyxohexosamine, but the theory of its structure will be proven beyond dispute after either a ribohexosamine or the other lyxohexosamine are synthesized. Unfortunately it will be a very difficult task to complete the series of theoretically possible aminohexoses. After addition of prussic acid to the pentosimines there appears only one form of hexosaminic acid, or the equilibrium of the two is so much in favor of one that the isolation of the other is not possible.

There is recorded only one successful attempt to prepare synthetically a hexosamine. Fischer and Leuchs¹ prepared glucosamine. They identified the sugar by its osazone and by the phenylisocyanate derivative. Neither the free sugar nor a simple salt of it have been obtained, because of the difficulty of the task.

The difficulty lay in the fact that the reaction product containing the sugar contained also a great excess of sodium sulfate and the unreduced lactone, and perhaps some of the unchanged amino-acid. The presence of the amino-acid and of its lactone hinders the crystallization of the acyl derivatives, while the presence of sodium sulfate renders the isolation of a salt of the amino sugar very difficult at the best.

It was found more convenient to carry out the reduction of the lactones in a hydrochloric acid solution. Both sodium and potassium amalgam were used as reducing agents. This mode of procedure proved very effective at least for two sugars, gluco-

¹ Fischer, E., and Leuchs, H., *Ber. chem. Ges.*, 1903, xxxvi, 24.

samine and lyxohexosamine. It did not improve conditions in the isolation of xylohexosamine.

The first experiments in the reduction of glucosaminic acids were accomplished by means of electrolytically prepared potassium amalgam. Indeed, in the very first experiment it was possible to isolate a small quantity of glucosamine containing only 2.5 per cent of ash. However, the same conditions could not be duplicated for the present, and all the later reductions and all the reductions of the lactones of lyxohexosaminic and of xylohexosaminic lactones were accomplished by means of a 2.5 per cent sodium amalgam.

Glucosamine.—The reduction of glucosaminic acid was carried out principally for the sake of method. As already stated, when potassium amalgam was employed as reducing agent and methyl alcohol used for fractionation, a fraction was obtained which contained only 2.5 per cent potassium chloride. When sodium amalgam was employed it was possible to separate the reaction product into one fraction which contained besides the sugar only sodium chloride, leaving all the unchanged lactone, amino-acid, and part of the sugar in solution. The first fraction contains approximately 50 per cent of the sugar present in the reaction mixture.

From the first fraction the isolation of a pure benzoyl derivative offers no difficulty at all, and the pentabenzoyl derivative of glucosamine was obtained in good yield. On the contrary, from the second fraction containing 50 per cent of the sugar only a fraction of a gram of the benzoyl derivative was isolated. The benzoyl derivative of course is readily converted into the free sugar.

Xylohexosamine.—The lactone was reduced in hydrochloric acid solution with sodium amalgam. For the present no successful fractionation of the reaction product was accomplished. The hydrochloride of the sugar is apparently very soluble in methyl alcohol. The sugar was identified by the osazone which possessed the melting point and the optical rotation of gulosazone. The pentabenzoyl derivative was obtained in rather poor yield. The yield of the naphthylisocyanate derivative was also rather poor; hence its purification was not accomplished for the present.

Lyxohexosamine.—The synthesis of this sugar was of immediate

importance in view of its bearing on chondrosamine. By recrystallizing the osazone of chondrosamine from pyridine and water it acquired the properties of galactosazone. Also the lyxohexosamine gave an osazone undistinguishable from galactosazone. Furthermore, the anhydromucic acid obtained from lyxohexosamine and from chondrosamine seem to be identical. On the other hand, the hydrochlorides of the two amino sugars were totally different in their melting points and their optical rotation. On the basis of the existing evidence the two sugars appear as epimeres of the following structure.

EXPERIMENTAL PART.

Glucosamine.—For the preparation of all lactones of hexosaminic acids it is important to start with very pure material. The glucosaminic acid used in these experiments was recrystallized several times out of water. 5.0 gm. lots of the acid were taken up in 50.0 cc. of 99.5 per cent alcohol. Dry hydrochloric acid gas was passed in, in a lively stream. The acid soon dissolved. After a while a flocculent precipitate begins to appear; if the solution is actively shaken during this phase nearly all the flocculent precipitate of the esters disappears. For a while the solution remained clear and then turned quite opaque. At this stage it was found advisable to immerse the flask in a cooling mixture and to continue passing the gas. Soon a precipitate of the lactone appeared. This was allowed to stand over night in the refrigerator. One can wash the lactone by decantation with 99.5 per cent alcohol and with dry ether and finally filter the lactone and dry it in a vacuum desiccator. It is then possible to

continue the work on the pure lactone. However, it was found that this mode of procedure had no advantage over the less troublesome method of Fischer and Leuchs. In most of the experiments the latter method was followed.

Isolation of Glucosamine Hydrochloride.—5.0 gm. of the lactone hydrochloride were reduced with 40.0 gm. of potassium amalgam (2 per cent), hydrochloric acid being used for neutralization. The reduction was carried out in a vessel immersed in a cooling mixture and provided with a mechanical stirrer. At the end of the experiment the solution tested with Fehling's reagent showed a reduction equivalent to 1.9 gm. of glucose. The reaction product was concentrated nearly to dryness. The residue was taken up in about 30.0 cc. of methyl alcohol and concentrated hydrochloric acid was added drop by drop. The flask was carefully warmed over flame until the syrupy material was all in solution and the salt had the appearance of a white crystalline powder. The salt was filtered. It showed the presence of considerable sugar, judging by its reducing power towards Fehling's solution.

The mother liquor on standing in the refrigerator formed a precipitate of practically pure glucosamine hydrochloride.

0.1030 gm. substance gave 0.1246 gm. CO_2 , 0.0600 gm. H_2O and 0.0026 gm. (2.55 per cent) ash.

	Calculated for $\text{C}_6\text{H}_{13}\text{NO}_3\cdot\text{HCl}$:	Found:
C.....	33.40	33.85
H.....	6.54	6.69

In a few other experiments the sugar contained more salt. This experiment goes to show that there can be found favorable conditions for the isolation of glucosamine hydrochloride directly from the reaction product.

Preparation of the Pentabenzoyl Derivative.—The material used for this preparation was obtained from several reduction experiments. Potassium and sodium amalgam were used for reduction and hydrochloric acid for neutralization. The reaction product was treated as in the above experiment. The fraction containing only sugar and salt was used for benzoylation.

6.5 gm. of the sugar (estimated by means of Fehling's solution) were taken up in 140.0 cc. of water, 25.0 cc. of benzoyl chloride,

and 40.0 cc. of a 50 per cent sodium hydrate solution. It was shaken for about $1\frac{1}{2}$ hours with constant cooling, and then placed in a shaking machine over night. The benzoyl derivative, which had the appearance of dry white balls, was washed with water, then dissolved in chloroform, and shaken with water in a separatory funnel. Finally the chloroform solution was dried over sodium sulfate, filtered, and concentrated to dryness. The residue was recrystallized out of 4 liters of 98 per cent alcohol. On cooling, the substance crystallized in long colorless needles. The mother liquor on concentration gave a second precipitate. The substance melted at 216°C . and had the following composition.

0.1012 gm. substance gave 0.2606 gm. CO_2 and 0.0453 gm. H_2O .

0.2530 " " required for neutralization by the Kjeldahl method
5.05 cc. 0.1 N acid.

	Calculated for $\text{C}_8\text{H}_8\text{NO}_3 (\text{C}_6\text{H}_5\text{CO})_2$	Found:
C.....	70.38	70.23
H.....	4.73	5.00
N.....	2.00	1.99

The optical rotation of the substance in pyridine was as follows:

$$[\alpha]_{\text{D}}^{20} = \frac{+0.58^{\circ} \times 1.9992}{0.5 \times 0.0522} = +44.4^{\circ}$$

The benzoyl derivative has been converted into the hydrochloride of glucosamine by previous workers; hence it was not considered important to repeat it on this occasion.

Xylohexosamine.—The lactone was prepared in the same manner as that of glucosaminic acid. Also in the reduction the general plan was followed. However, all the attempts to obtain a fraction free from the lactone were for the present unsuccessful. When hydrochloric acid was used for neutralization the salt always separated out free from sugar, and when sulfuric acid was employed for the same purpose salt, lactone, and sugar crystallized in the same fraction.

A solution containing about 6.0 gm. of the amino sugar and 1.0 gm. of amino nitrogen was taken up in 500 cc. of water to which 80.0 cc. of benzoyl chloride and 110 cc. of a 50 per cent sodium hydrate solution were added. The benzoylation proceeded as in the glucosamine experiment. The final product was taken up

in methyl alcohol and ether was added as long as it caused the precipitation of an oil. The supernatant liquid was decanted and allowed to evaporate spontaneously. A precipitate of white needles formed. It was filtered off and recrystallized once out of 99.5 per cent alcohol. It melted at 162°C. and had the following composition.

0.1012 gm. substance gave 0.2632 gm. CO₂ and 0.0416 gm. H₂O.

	Calculated for C ₈ H ₁₃ NO ₃ (C ₆ H ₅ CO) ₂ :	Found:
C.....	70.38	70.93
H.....	4.73	4.60

The rotation of the substance was the following:

$$[\alpha]_D^{20} = \frac{+1.1^\circ \times 1.9422}{0.5 \times 0.0550} = +77.6^\circ$$

Osazone of Xylohexosamine.—A solution containing 2.5 gm. of the amino sugar was taken up in 250 cc. of water and 6.0 gm. of phenylhydrazine dissolved in glacial acetic acid were added. The flask containing the solution was then placed in boiling water bath for 4 hours. On cooling, the osazone settled out. It was recrystallized four times out of water and pyridine. It then consisted uniformly of curved needles. The substance was taken up in a very little alcohol and ether. It dissolved and crystallized on evaporation of the solvent in the form of bright lemon yellow precipitate. It melted at 173° (corrected) and decomposed at 185°C.

The substance had the following composition.

0.1000 gm. substance gave 0.2208 gm. CO₂ and 0.0560 gm. H₂O.

	Calculated for C ₁₈ H ₁₇ N ₅ O ₄ :	Found:
C.....	60.33	60.21
H.....	6.14	6.22

The rotation of the substance was as follows:

0.1000 gm. substance dissolved in 5.0 cc. of Neuberg's alcohol-pyridine solution had an initial rotation of $\alpha = +0.07^\circ$ and after 40 hours $\alpha = +0.45^\circ$.

The naphthylisocyanate derivative was not obtained in pure form. We intend to report on the phenyl and naphthylisocyanate derivatives of the hexosamines on another occasion.

Lyxohexosamine.—15.0 gm. of lyxohexosaminic acid were taken up in three small flasks, each containing 5.0 gm. of the acid and 50.0 cc. of 99.5 per cent alcohol. Into each a lively stream of dry hydrochloric acid gas was passed. The formation of the lactone proceeded in the same way as with the glucosaminic acid. The flasks were allowed to stand over night, then transferred to a distilling flask by the aid of distilled water. 150.0 gm. of 2.5 per cent sodium amalgam were used for reduction. At the end of the experiment the solution tested with Fehling's reagent showed a reduction equivalent to 6.5 gm. of glucose.

The product of reaction was concentrated under diminished pressure to dryness. The residue was taken up in 75.0 cc. of methyl alcohol and concentrated hydrochloric acid added drop by drop until all the syrup dissolved and sodium chloride appeared in the form of white crystalline powder. This first precipitate showed no reducing power at all.

The filtrate was again concentrated to dryness and taken up in 99.5 per cent ethyl alcohol and hydrochloric acid as before. On standing, an oily mass separated out. In course of the night this turned to a crystalline mass. The supernatant liquid was decanted and the crystalline mass triturated with methyl alcohol. It consisted of long heavy prisms with needle-shaped points. The substance burned as carbohydrates do and left behind a small amount of ash. The liquid which had been decanted off the crystalline mass on standing began to form on the walls and on the bottom of the flask a crystalline deposit consisting of long prisms of the same appearance as those of the crystalline mass. On burning it left practically no ash.

The substance was redissolved in a little water and 99.5 per cent alcohol added in small portions until on scratching the sugar began to crystallize. The crystals had the same appearance as on first crystallization. The substance melted at 185°C. (corrected), and had the following rotation:

$$[\alpha]_D^{25} = \frac{\text{Initial}}{1.0 \times 0.0485} = +62.69^\circ \quad [\alpha]_D^{25} = \frac{\text{Equilibrium.}}{1.0 \times 0.0485} = +91.10^\circ$$

0 1050 gm. substance dried in a vacuum desiccator over sulfuric acid at 25°C. gave 0 1284 gm. CO₂ and 0 0604 gm. H₂O.

0 0244 gm. substance gave 2 94 cc. N at 22°, 762 mm.

0 0820 " " required 3 7 cc. 0 1 N AgNO₃ solution.

	Calculated for $C_{12}H_{13}O_5N.HCl$:	Found:
C.....	33.40	33.35
H.....	6.54	6.39
N.....	6.51	6.74
Cl.....	16.45	15.98

The mother liquor of the crystalline mass was concentrated under diminished pressure. It contained 3 gm. of sugar and was taken up in 400 cc. of water, 8.0 gm. of phenylhydrazine dissolved in glacial acetic acid were added, and the flask containing the solution was immersed in a boiling water bath for 4 hours. The osazone began forming while the solution was still heated. On cooling, a voluminous precipitate of osazone deposited. The osazone was taken up in 400.0 cc. of boiling water and pyridine was added gradually (the water was kept boiling) until the solution was complete. After three recrystallizations microscopic slides showed perfectly formed elongated plates with pointed ends, and an absolute absence of oily droplets. The osazone was then filtered on a suction funnel, transferred into a mixture of equal parts of alcohol and ether, and filtered. It then had the appearance of light orange glistening plates.

It melted at 201°C. and decomposed at 202° (corrected). Mixed with osazone from chondrosamine and with galactosazone it showed the same melting and decomposition points.

0.1006 gm. substance gave 14.2 cc. N at 29° and 757 mm.

	Calculated for $C_{12}H_{13}N_4O_5$:	Found:
N.....	15.64	15.80

For the rotation of the substance 0.050 gm. was dissolved in 5.0 cc. of Neuberg's pyridine and alcohol mixture. The initial rotation was +0.36°, after 24 hours, +0.03°. (It was not followed further.)

Another sample of osazone which had been recrystallized out of 85 per cent alcohol and which dissolved more readily, though with considerable difficulty, showed the following rotation:

0.100 gm. substance dissolved in 5.0 cc. of alcohol-pyridine solution gave an initial rotation of +0.56°, and an equilibrium of +0.16°.

From a smaller experiment a benzoyl derivative was obtained in the same manner as from xylohexosamine. However, the quantity was too small for recrystallization.

THE PHYSIOLOGICAL ACTION OF GLUCAL.

By J. O. BALCAR.

(From the Hull Laboratory of Biochemistry, The University of Chicago.)

(Received for publication, June 27, 1916.)

The exact nature of the intermediate forms through which glucose passes before it is finally broken up by the animal body during metabolism is still a matter of question and needs further investigation. In view of this fact it was thought highly essential that a substance like glucal, $C_6H_{10}O_4$, which is so closely related to glucose, in fact derived from it, be studied in reference to its behavior in the animal body. The possibility that glucal may be an intermediate stage of glucose metabolism is supported by the facts that glucal is derived from glucose by reduction and dehydration and that it is quite unstable. Nef¹ states that the structural formula of glucal is:

If this formula is correct it lends support to the theory that glucal may be an intermediate product of glucose metabolism, for a substance possessing such a structure by its very nature indicates that it may be readily transformed into other derivatives.

It may also be mentioned here that Feulgen² suggests glucal as the carbohydrate of nucleic acid.

The work and the results recorded here by no means settle the question whether or not glucal is an intermediate product of glucose metabolism. However, a number of positive results have been obtained which may prove of assistance in future work on this problem.

¹Nef, J. U., *Ann. Chem.*, 1914, cdiii, 334.

²Feulgen, R., *Z. physiol. Chem.*, 1914, xcii, 154.

The Preparation of Glucal.

The glucal used in the experiments recorded was prepared according to the methods given by Fischer³ except for the saponification of the acetyl groups of the acetyl derivative.

According to Fischer the saponification of the acetyl groups of the triacetyl glucal is carried out with barium hydroxide. The barium is removed by precipitation with sulfuric acid and filtering. Glucal is very unstable in an acid solution, so that great precaution must be taken not to make the solution acid with an excess of sulfuric acid. In taking this precaution lies the danger that not all the barium is removed and so may be present in the final product. Barium itself is toxic.

In order to obviate the possibility of barium poisoning, then, the triacetyl glucal was saponified with sodium hydroxide. The exact procedure was this: 5 gm. of dry crystalline triacetyl glucal were finely powdered and treated with 130 cc. of 0.5 N sodium hydroxide. This mixture was shaken on a machine for 2 hours. To the solution were then added 130 cc. of 0.5 N sulfuric acid. Thus far the process was carried out at room temperature. The solution then was distilled under reduced pressure at 40°C. till the separation of salts occurred. The glucal then was extracted three times with 100 cc. portions of absolute alcohol. The latter was distilled off under reduced pressure, leaving the final product, glucal, as a colorless syrup. This again was taken up with 100 cc. of absolute alcohol and the latter distilled off as before. The syrup was then dissolved in water which had been boiled for 10 minutes. Thus a sterile solution of glucal was prepared. Any acidity due to incomplete removal of acetic acid was neutralized with 0.1 N NaOH. (The trace of sodium acetate thus formed is physiologically inactive.) By this method 5 gm. of triacetyl glucal yielded on an average 2.5 gm. of glucal.

³Fischer, E., *Ber. chem. Ges.*, 1914, xlvii, 196.

The Chemical Characteristics of Glucal, Its Molecular Formula, and Its Probable Structural Formula.

The glucal prepared in the manner described possessed the following characteristics:

1. On treatment with strong mineral acids it formed a dark char.
2. On treatment with strong alkalis it turned yellow.
3. In a water solution a dark green precipitate was formed on the addition of concentrated sulfuric or hydrochloric acid.
4. It could readily be detected in urine by the formation of a dark green precipitate when 1 cc. of the glucal containing urine was diluted with 5 cc. of water, and 2 cc. of concentrated sulfuric acid were added. Samples of urine containing glucal in the proportion of 1 gm. of glucal to 1 liter of urine gave the test well.
5. The glucal recolored fuchsin sulfurous acid.
6. Iodine and bromine were rapidly absorbed by glucal. The glucal iodine combination did not color a 1 per cent starch solution.
7. The glucal reduced Fehling's and Haines' solutions.
8. On treatment with sodium acetate and acetic anhydride, glucal was transformed into triacetyl glucal.

The molecular formula of glucal is $C_6H_{10}O_4$. There are various opinions as to its structural formula. Fischer suggests that it is constructed in this manner:

Nef states that it has this structure:

Judging from the character of the reactions which take place in the formation of glucal *in vitro* it would seem that the Nef formula was the correct one. For when acetobromoglucose is treated with zinc, it yields one molecule of hydrobromic acid and one

molecule of acetic acid. We may then represent the reaction thus ($\text{Ac} = \text{CH}_3\text{CO}$):

The saponification of the acetyl groups of the triacetyl derivative may be represented in this manner:

It may then be assumed that the lactone ring is of an oscillating type because of the instability of glucal. Accordingly the product may be transformed from a γ lactone compound to a β lactone.

Thus a product having the formula as given by Nef would be produced. This formula accounts for all the reactions of glucal as given according to Fischer except the pine splinter reaction indicating a furane ring. However, the chemical composition of the substance in a pine splinter giving the reaction is not definitely known. Consequently, in the opinions of some, a furane

compound may not be the only compound producing green coloration of a pine splinter moistened with hydrochloric acid.

Experiments on the Physiological Action of Glucal.

The first two experiments were conducted solely for the purpose of determining whether glucal is a toxic compound or not. In the first experiment a 2 per cent solution was injected subcutaneously into six frogs as indicated:

Weight.	Dose.	Time.	Results.	
			Immediate.	Later.
<i>gm.</i>	<i>cc.</i>			
56	4	2.56	No change.	No change.
42	3	3.00	" "	" "
37	2.5	3.10	" "	" "

Controls, using water instead of glucal solution.

30	2.6	3.17	No change.	No change.
38	4	3.18	" "	" "
60	5	3.20	" "	" "

The frogs showed no symptoms of poisoning such as morbidity, muscular twitching, or spasms as a result of the injection of glucal. Their behavior at all times was normal.

From these results we may conclude that glucal injected subcutaneously into frogs in doses of 1.4 mg. per 1 gm. of body weight produces no toxic effects.

In the second experiment, a guinea pig weighing 250 gm. was injected subcutaneously with 5 cc. of a 10 per cent solution of glucal. The animal showed no effects of poisoning locally or systemically, immediately or at any time afterwards.

Next an experiment was carried out to determine the effect of glucal on respiration and blood pressure. A dog weighing 8 kilos was anesthetized with ether. A cannula was inserted into the trachea and connected with a respiration tracing apparatus. Also a cannula inserted into the right carotid artery was connected with a blood pressure mercury manometer. Tracings of both movements were taken; *i.e.*, respiration and blood pressure. The

blood pressure was 130 mm. Hg and the respiration normal in each of the following five intravenous injections.

	Time.
5 cc. M/8 Na acetate.....	3.14
5 " 10 per cent glucal.....	3.16
5 " 10 " " "	3.21
5 " 10 " " "	3.23

The dog was observed for an hour but no deviation from the normal state occurred.

Also an experiment on the metabolism of glucal in the animal body was carried out in the following manner:

A dog, not anesthetized, weighing 10 kilos, was injected with 6.5 gm. of glucal, with a Woodyatt continuous injection machine, by way of the left saphenous vein at the rate of 0.9 gm. per kilo of body weight per hour. The dog showed no ill effects during the operation or afterwards. The urine, collected by catheter, was examined as indicated:

Test.*	Before glucal injection.	After glucal injection.
H ₂ SO ₄	Pink, clear.	Green precipitate.
Reduction (Haines' solution).....	None.	Slight.
H ₂ SO ₄	1 cc. of urine + 0.01 cc. of a 10 per cent solution of glucal diluted with 5 cc. of water gave a green precipitate.	

* Glucose does not give this test with sulfuric acid.

Then we may conclude that glucal injected into the venous system of an animal is not totally metabolized if injected at the rate of 0.9 gm. per kilo per hour. This is the limit of tolerance of the injection of glucose under similar conditions. Whether any of the glucal was metabolized could not be estimated, since thus far no accurate method of determining glucal in solution has been developed. It is hoped that this may be accomplished by bromine or iodine titration.

It is possible that if glucal is formed from glucose in the animal body, a reversible process may also take place in case of an excess over the normal tolerance of glucal, such as has been observed

in the above experiment. Therefore it seemed important that for future work some test for glucose be established distinguishing it from glugal, and not clouded by the reaction of the latter. Since one of the common methods employed for determining the presence of glucose is the fermentation test, it has been of interest to determine whether or not glugal is fermentable.

Accordingly a 1 per cent peptone and 0.3 per cent bouillon broth was prepared. Its reaction was adjusted so that 5 cc. of the broth exactly neutralized 1 cc. of 0.05 N NaOH. 13.5 cc. were placed in each of eighteen fermentation tubes. The tubes were divided into sets of six. To one of the three sets thus formed were added 1.5 cc. of a 10 per cent glugal solution, per tube; to another, 1.5 cc. of a 10 per cent glucose solution, per tube; and to the third, 1.5 cc. of distilled water per tube. (The solutions containing the glucose and those containing the water additions were sterilized together with their respective additions. The tubes later containing glugal were sterilized before the latter was added because of the instability of glugal at high temperatures. The glugal additions, however, were also sterile, since the glugal had been obtained from an alcohol extract and dissolved in water which had previously been boiled for 10 minutes.)

Then three tubes of each set were inoculated, each with one loopful of a pure culture of *Bacillus coli*. The other three tubes of each set were inoculated with one loopful of a pure culture of *Saccharomyces cerevisiæ*. The following is a record of the procedure and results (temperature 35°C.):

Tube.	Substance tested.	Organism.	Results. Gas.		
			12 hrs.	24 hrs.	36 hrs.
	cc.				
1	1.5 10 per cent glucal.	<i>Bacillus coli.</i>	0	0	0
2	1.5 10 " " "	" "	0	0	0
3	1.5 10 " " "	" "	0	0	0
4	1.5 10 " " "	Yeast.	0	0	0
5	1.5 10 " " "	"	0	0	0
6	1.5 10 " " "	"	0	0	0
7	1.5 10 " " glucose.	<i>Bacillus coli.</i>	2 cm.	2.5 cm.	2.5 cm.
8	1.5 10 " " "	" "	2 "	2.5 "	2.5 "
9	1.5 10 " " "	" "	2 "	3 "	3 "
10	1.5 10 " " "	Yeast.	0	3 "	3 "
11	1.5 10 " " "	"	0	2.5 "	2.5 "
12	1.5 10 " " "	"	Bubble.	2.5 "	2.5 "
13	1.5 water.	<i>Bacillus coli.</i>	0	0	0
14	1.5 "	" "	0	0	0
15	1.5 "	" "	0	0	0
16	1.5 "	Yeast.	0	0	0
17	1.5 "	"	0	0	0
18	1.5 "	"	0	0	0

There were definite growths of the organisms in all the tubes in 24 hours. The yeast cells of the tubes containing glucal were examined microscopically after 24 hours, and budding forms of the cells could be seen.

The results indicate that glucal is fermented neither by *Bacillus coli* nor by *Saccharomyces cerevisiae*. The fermentation test then may be used in distinguishing between glucose and glucal.

In summary, the above recorded results indicate that:

1. Glucal is not a toxic substance.
2. Glucal produces no effect on blood pressure or on respiration when injected intravenously in moderate quantities.
3. Glucal may be detected in urine with concentrated sulfuric acid.
4. Glucal combines with iodine and the combination does not color a 1 per cent starch solution.
5. The animal body does not completely metabolize glucal when the latter is injected at the rate of 0.9 gm. per kilo per hour.
6. Glucal is not fermented either by *Bacilli coli* or *Saccharomyces cerevisiae*.

I wish to express my gratitude for the valuable suggestions and assistance of Dr. Mathews, who suggested the problem, and to Drs. Koch, Wilder, and Woodyatt, and Messrs. Hanke and Theobald.

THE FORMATION OF *d*-LACTIC ACID BY THE AUTOLYSIS OF PUS.

By HIIZU ITO.

(From the Institute of Medical Chemistry of the Kyoto Imperial University,
Kyoto, Japan.)

(Received for publication, June 19, 1916.)

That a lactic acid is present in pus was accidentally found by Tatsukichi Irisawa.¹ Though he stated, "Ferner habe ich gelegentlich aus etwa einem Liter frischen Empyemeiters eine kleine Quantität Milchsäure dargestellt," he gave no further description of his work. It was, therefore, impossible to decide what form of the lactic acid was found by him. An attempt was made by the writer to determine the form and to ascertain whether the *d*-lactic acid was formed by the autolysis of pus. The pus obtained from the pleura was used in the experiments.

The method of Professor Yoshikawa was adopted with modifications. An equal quantity of pus was taken in each of two flasks and that in one flask was mixed with five times as much 90-95 per cent alcohol. After standing for 24 hours it was filtered. The residue was thoroughly washed with alcohol. After the alcohol was evaporated, the residue, acidified with phosphoric acid, was extracted as much as possible with ether in Sudo's apparatus. After the ether was evaporated on a water bath, the syrup which remained was boiled with a little water and lead carbonate, filtered, and washed with water. The lead was removed from the filtrate, passing hydrogen sulfide through it. After the filtrate was strongly concentrated on the water bath, lactic acid was extracted with ether. After the ether was evaporated, the lactic acid was transformed into lithium lactate by boiling with water and lithium carbonate. The lactate solution was transferred into a 25 cc. flask and water was added to it to the 25 cc. mark. The solution was shaken and filtered, and examined with the polariscope.² The pus of the second flask was digested with toluene and chloroform at 37-38°C. for 4 days. The procedure of extracting the

¹ Irisawa, T., *Z. physiol. Chem.*, 1893, xvii, 349.

² Yoshikawa, J., *Z. physiol. Chem.*, 1913, lxxxvii, 389.

lactic acid from the digested material was the same as with the first portion. But in the last two cases of the series which follow, the method of Mondschein, which was modified by Yoshikawa,² was adopted as the method of extracting the lactic acid, because it was suggested to the writer that Mondschein's method would give a better result than the alcohol extraction. In these cases, one portion of the pus was mixed with five times as much water. To precipitate the protein content, the mixture, to which was added a weak acetic acid, was boiled for 30 minutes and filtered through "nutsch." The residue was warmed with 50 cc. of water and 15 cc. of 15 per cent NaOH, which dissolved the former. The solution was then neutralized with weak sulfuric acid and filtered. This filtrate was put together with the other which was prepared through the "nutsch." The whole filtrate was concentrated to a syrup, and was extracted with 95 per cent alcohol, which was entirely evaporated. The residue was strongly acidified with phosphoric acid and was extracted with ether in the extracting apparatus. The lactic acid which was obtained after the ether was evaporated was transformed into lithium lactate by adding water and lithium carbonate. The lithium lactate was treated as suggested by Yoshikawa and was examined with the polariscope. The calculation of the *d*-lactic acid from α was followed exactly as Yoshikawa suggests.

Patient.	Pus in each determination.	Lithium lactate obtained.		Lactate formed by autolysis
		At once.	After 4 days' autolysis.	
I. School boy, 19 years. Pus from chest after rib resection.	gm. 300	gm. 0.7370	gm. 0.8366	gm. 0.0996

VI. Man, 20 years. Pus from chest after rib resection.	250	0.1653	0.2665	0.1012

²Yoshikawa, *Z. physiol. Chem.*, 1913, lxxxvii, 406.

To determine finally that the lactic acid found in both portions was identical with *d*-lactic acid, the lithium lactate which was formed from the material experimented on was transformed into zinc lactate.

Transformation of Lithium Lactate into Zinc Lactate.

The lithium lactate solution which was obtained in the series of the first portion from all six cases was put all together. The solution was strongly acidified with phosphoric acid and was extracted with ether in Sudo's apparatus. After the ether was evaporated, the residue was diluted with water, boiled with pure lead carbonate, filtered, and washed well. The lead was taken away from the filtrate with hydrogen sulfide; the solution with no lead was strongly concentrated on the water bath, and was extracted as much as possible with ether. After the ether was evaporated the residue was boiled with water and pure zinc oxide, filtered, and washed thoroughly. The filtrate with the water used for washing was evaporated on the water bath until the zinc lactate began to crystallize. It was repeatedly recrystallized from hot water, until pure crystals were obtained. The crystals showed under examination the typical characteristics of the *d*-zinc lactate.

The quantity of unhydrated zinc lactate in the solution of 100 cc. was 2.6546 gm.; length of the tube, 2 dm.; rotation, using sodium light, at $19^\circ = -0.438^\circ$. Therefore: $[\alpha]_D^{19} = -8.25$.

0.2126 gm. substance lost at 110°C .	0.0278 gm. H_2O .
0.1154 " " gave	0.0384 " ZnO .
0.1322 " " lost at 110°C .	0.0168 " H_2O .
0.1848 " " gave	0.0613 " ZnO .

	Calculated for $(\text{C}_3\text{H}_5\text{O}_2)_2\text{Zn} + 2 \text{H}_2\text{O}$:	1.	Found: 2.
H_2O	12.9	13.08	12.71
Zn	26.86	26.69	26.62

The zinc lactate experimented on was thus shown to be identical with *d*-zinc lactate.

The quantity of unhydrated zinc lactate in the solution of 100 cc. was 2.7823 gm.; length of the tube, 2 dm.; rotation, using sodium light, at $15^\circ = -0.446^\circ$. Therefore: $[\alpha]_D^{15} = -8.01$.

0.1275 gm. substance lost at 110°C. 0.0165 gm. H₂O.

0.3742 " " gave 0.1246 gm. ZnO.

	Calculated for (C ₃ H ₅ O ₂) ₂ Zn + 2 H ₂ O:	Found:
H ₂ O.....	12.9	12.94
Zn.....	26.86	26.75

The zinc lactate obtained in the second portions was thus shown to be identical with *d*-zinc lactate.

SUMMARY.

1. *D*-lactic acid is a constant constituent of pus.
2. *D*-lactic acid is distinctly increased by the autolysis of pus.

THE ORIGIN OF THE HUMIN FORMED BY THE ACID HYDROLYSIS OF PROTEINS.

II. HYDROLYSIS IN THE PRESENCE OF CARBOHYDRATES AND OF ALDEHYDES.

By ROSS AIKEN GORTNER.

(From the Division of Soils, Minnesota Agricultural Experiment Station,
St. Paul.)

(Received for publication, June 9, 1916.)

INTRODUCTION.

In a recent article (Gortner and Blish, 1915) the statement was made that "in all probability the humin nitrogen of protein hydrolysis has its origin in the tryptophane nucleus." This statement was based upon the following findings.

1. Zein, which contains no tryptophane, yields but a very small amount of humin nitrogen on hydrolysis (compare also Osborne and Jones, 1910).

2. *When tryptophane was added to zein and the mixture hydrolyzed, a very considerable quantity of humin nitrogen was produced.*

3. This humin was formed from tryptophane *plus* some other product of protein hydrolysis, inasmuch as the formation of humin from 1 gm. of zein plus tryptophane had reached a maximum where 0.125 gm. of tryptophane had been added, and the addition of tryptophane in excess of this amount failed to increase the humin nitrogen.

4. When tryptophane was heated with hydrochloric acid in the presence of a carbohydrate 86.56 per cent of the tryptophane nitrogen was recovered in the humin, and we suggested that perhaps the reaction involved in the humin formation was the condensation of an aldehyde with the $-NH$ group of the tryptophane nucleus (compare also Homer, 1913, a).

5. We suggested that it might be possible so to alter the conditions of hydrolysis as to make the tryptophane plus carbohydrate reaction a quantitative method for the determination of

tryptophane, and stated that we did not have sufficient material at that time to work out the ideal conditions of the reaction.

6. We found that the adsorption of ammonia by the non-nitrogenous humin formed from carbohydrates could not be an important factor in the formation of humin nitrogen.

These findings were later confirmed in part and accepted by Osborne, Van Slyke, Leavenworth, and Vinograd (1915), and by Van Slyke (1915), these authors accepting the humin nitrogen formed in the presence of carbohydrate as representing 86 per cent of the tryptophane nitrogen present in the original protein. Later, Grindley and Slater (1915) took strong exception to our findings and state: "Unfortunately for the good of the methods for the analysis of proteins the conclusion of Gortner and Blish that in all probability the humin nitrogen of protein hydrolysis has its origin in the tryptophane nucleus is apparently not true, since humin contains in addition adsorbed nitrogen from other amino acids."

It seems to me that this is a rather sweeping statement to make in the face of findings (1) and (2) noted above. Had Grindley and Slater expressed doubts as to the humin nitrogen being a *quantitative* measure of the tryptophane content of the protein, or that other humin formed in the presence of carbohydrate was a quantitative measure of tryptophane, I should probably agree, inasmuch as we stated definitely that our data did not permit us to state the conditions under which a quantitative conversion of tryptophane to humin could be obtained. It is to be regretted if our statement, "When an abundance of carbohydrate is present nearly 90 per cent of the tryptophane nitrogen remains in the humin nitrogen fraction. It is suggested that this property be utilized to determine the approximate quantity of tryptophane in proteins," conveyed the idea that we put this forward as a quantitative method. What we intended to suggest was that some one should utilize this property to elaborate a method which would be quantitative. Inasmuch as no one has attempted to do this, I have again taken up the problem and, as will be shown below, have found that carbohydrates cannot be used. However, I still believe (due to observations (1) and (2) above) that our original conclusion is very near the truth; i.e., "in all probability the humin nitrogen of protein

hydrolysis *has its origin* (at least in part) in the tryptophane nucleus." In making this statement we were thinking of the hydrolysis of a *pure protein* to which nothing had been added.

At this point it may be well to consider the material with which Grindley and Slater worked, the results from which apparently caused them to question our findings. They subjected blood meal, tankage, alfalfa hay, white soy beans, cottonseed meal, oats, barley, rolled wheat, and whole wheat to acid hydrolysis and *proceeded with the analysis of the resulting hydrolysate, using Van Slyke's method, in exactly the same manner as though they were dealing with a pure protein.* They express the results obtained from the basic fraction as "arginine N," "cystine N," "histidine N," and "lysine N." What justification is there for this? Indeed what justification is there for their term "humin nitrogen" if by humin nitrogen we mean the nitrogen originating from protein material by acid hydrolysis? Van Slyke (1915) recently called attention to the fact that his methods were devised to be applied to pure protein material and not to a heterogeneous mixture of nitrogen compounds. To be sure many valuable *comparative* data can be obtained by the application of Van Slyke's methods to heterogeneous material, and I have already (1913) used them in this connection, being careful to state that the "arginine," "histidine," etc. were not necessarily pure arginine and histidine, but that the nitrogen of these fractions reacted in the same manner as arginine or histidine nitrogen of a protein, and that the results, while not *exact*, were *comparative* when compared with similar material.

In this connection it is of interest to note the findings of Janney (1916) on the protein content of muscle. He states that approximately *13 per cent of the nitrogen of muscle is combined in non-protein substances.*

If muscle contains such a large percentage of non-protein nitrogen, it seems very probable that in the material analyzed by Grindley and Slater, there must have been many nitrogenous organic compounds which had no relation to the protein molecule, such as nitrogenous fats, nitrogenous pigments, purine bases, pyrimidine bases, etc. How will these behave to acid hydrolysis? How will they be distributed in the subsequent distribution by Van Slyke's method? For *comparative* results

these questions need not be answered, but it is self-evident that *no direct analogy can be drawn between the analysis of a protein mixed with an unknown amount of these nitrogenous compounds and the analysis of pure proteins.* It is certain that the humin nitrogen will be altered to a marked extent by the presence of many of these compounds; the humin nitrogen of such a mixture represents the sum total of all the nitrogenous compounds which are insoluble in hot water or dilute calcium hydroxide, together with calcium salts of nitrogenous organic acids or the purine or pyrimidine bases in addition to the humin formed from the protein present. The humin nitrogen (from protein material) actually present in such a mixture may easily be a very small part of the nitrogen found. This is equally true of the "humin nitrogen" reported by Potter and Snyder (1915) for the hydrolysate of certain soils and soil extracts. In one instance the "humin nitrogen" attains to 21.5 per cent of the total nitrogen. It is perfectly obvious that while Potter and Snyder's results are extremely valuable as *comparative* results, they do not give us exact data regarding the nature of the proteins present in the soil. The actual arginine, histidine, and lysine present in the soil would probably differ widely from the quantities indicated by the method of analysis *because this method gives accurate data regarding amino-acids only when applied to the analysis of pure protein.*

I have shown (1913) that uric acid nitrogen is distributed after acid hydrolysis 15.3 per cent as ammonia nitrogen, 35.98 per cent as humin nitrogen, 12.97 per cent as basic nitrogen, and 35.78 per cent in the filtrate from the bases. The "humin nitrogen" in this instance contained no trace of black color and was probably calcium urate.

In this paper as well as in the previous one I am concerned only with the problem of *protein nitrogen* and I am ready to grant that in all probability the results already given, and those which will be given below, will not apply to the analysis of heterogeneous mixtures of nitrogenous compounds.

EXPERIMENTAL.

Throughout this work only one protein has been used. The protein selected was Merck's "fibrin from blood." This selection was made, partly because of the ease with which the material could be secured, and partly because analyses were already on record (Van Slyke, 1911) with which comparison could be made. A protein high in lysine was purposely chosen for reasons which will be shown later.

The tryptophane represented a part of the material, the analysis of which was reported in our previous paper (Gortner and Blish, 1915). The tyrosine was prepared from silk waste in the usual manner (Hoppe-Seyler, 1909) and was repeatedly recrystallized from hot water.

A. Hydrolysis of Protein in the Presence of Carbohydrates.

As far as I am aware, the only data dealing with the hydrolysis of a pure protein in the presence of carbohydrate material are those which have been reported from this laboratory (Gortner and Blish, 1915) and those reported in confirmation of these results by Osborne (1915). A summary of these data is given in Tables I and II.

The Hydrolysis of Fibrin in the Presence of Equal Amounts of Different Carbohydrates.—3 gm. of fibrin were boiled for 48 hours with an equal amount of dextrose, lactose, levulose, sucrose, maltose, cellulose (Swedish filter paper), and soluble starch (Merck's) in the presence of 75 cc. of 20 per cent HCl. Ammonia nitrogen and humin nitrogen were determined according to Van Slyke (1911), using the entire hydrolysate. The data are given in Table III.

It will be observed that, in every instance, the added carbohydrate approximately doubled the humin nitrogen while the ammonia figures are only slightly altered. It is probable that there is a very slight loss of ammonia nitrogen due to the added carbohydrate but this loss is practically negligible in a protein analysis. The 3 gm. of fibrin taken for analysis contained approximately 0.4550 gm. of nitrogen so that the maximum change of 0.00352 gm. ammonia nitrogen would equal only 0.77 per cent of the total nitrogen. That the actual change in the amount of ammonia nitrogen is considerably less than this is shown by a reference to Table IV where, in two duplicate determinations, 9 gm. of carbohydrate altered the ammonia nitrogen only 0.69 and 0.16 per cent of the total nitrogen. The last figure is well within the maximum error allowed by Van Slyke (1911), 0.37 per cent. It seems very probable, however, that the lower

* Omitted from average.

† Humin not determined in the usual manner on these solutions.

ammonia determination is due to a slower rate of hydrolysis when carbohydrates are present. Osborne (1915) states that hydrolysis is slower in the presence of carbohydrate material. A more rapid hydrolysis would have the same effect as a longer hydrolysis, and more ammonia N would be formed (compare Table VIII and footnote 2).

The increase in the humin nitrogen does not appear to be constant, but I believe that most of the variation is caused by unavoidable errors in the washing of the humin. In some instances the humin "balled" together, and it is possible that channels were formed so that the washing was incomplete. In some instances the filter practically clogged with a gummy humin, while in other instances the humin was granular and washed as fast as water could be poured through it. It was found near the end of the experiments that the amount of calcium hydroxide added in the ammonia determination determined, to a great

extent, the nature of the humin. In the presence of a large excess of lime the humin was usually gummy and filtered slowly, while the granular condition was obtained when the lime was present in only a slight excess. The table does show, however, that the ammonia nitrogen is not greatly changed by the added carbohydrate and that there is a fairly uniform increase in humin nitrogen regardless of the nature of the carbohydrate added.

Hydrolysis of Fibrin in the Presence of Increasing Amounts of Carbohydrate.—3 gm. of fibrin were hydrolyzed in the presence of 1.5, 3.0, 6.0, and 9.0 gm. of cellulose (Swedish filter paper) by boiling with 75 cc. of 20 per cent HCl for 48 hours. The ammonia and humin nitrogen data are shown in Table IV.

TABLE IV.

The Ammonia and Humin Nitrogen Obtained from 3 Gm. of Fibrin Hydrolyzed in the Presence of Increasing Amounts of Carbohydrate.

Swedish filter paper added.	Ammonia N.	Increase (+) or decrease (-)	Average change	Humin N.	Increase (+).	Average change	Average increase due to each 15 gm carbohydrate added
gm.	mg.		per cent	mg.		per cent	per cent
None(average)	46 42			13 13			
1 50	46.70	+0 28	+0.60	19 95	+ 6 82	51 94	51.94
3.0	46 90	+0 48		24 65	+11 52		
	45 90	-0 52	-0 09	23 80	+10 67	84 53	32 59
6 0	44.80	-1 62		29.35	+16 22		
	45 00	-1 42	-3 27	30 55	+17.32	127 7	21.59
9.0	43 30	-3 12		33 55	+20 42		
	45 70	-0 72	-4 14	34 85	+21 72	160 4	16 37

It will be observed that there is no uniform increase or decrease of the ammonia nitrogen due to the added carbohydrate, the figures obtained suggesting only chance variation.

The humin nitrogen, however, shows a continuous increase, but this increase is not a direct function of the added carbohydrate but seems to result from two or more reactions. On the addition of only 1.5 gm. of cellulose the humin nitrogen increased almost 52 per cent. This is nearly twice the increase due to the second 1.5 gm. (32.59 per cent). The increase in humin nitrogen continues to fall until there is average increase of only

16.37 per cent for the fifth and sixth 1.5 gm. of carbohydrate added.

If the mg. of humin nitrogen obtained are plotted against the gm. of added carbohydrate it will be found that a very regular curve is obtained, rising quite rapidly at first and then flattening out, with no indication of ever reaching a straight line maximum. This experiment seems to confirm Grindley and Slater (1915) in their statement that adsorption of amino-acids by the humin formed from carbohydrates must be taken into account. Adsorption, absorption, or occlusion must be the cause of at least a part of the continued increase. These factors, however, cannot explain the rapid increase of the humin nitrogen due to the first addition of carbohydrate, where the reaction is undoubtedly largely a chemical one.

Comparative Analyses of Fibrin Hydrolyzed Alone and in the Presence of Three Times Its Weight of Cellulose.—As noted earlier, Osborne (1915) hydrolyzed lactalbumin in the presence of an equal weight of dextrose and found that, aside from an increase in the humin nitrogen, there was no notable change in any of the other fractions. As regards the basic fractions they state: "The total nitrogen of the bases was not reduced at all nor are the proportions of amino to non-amino nitrogen in the bases significantly affected." Their analyses are reprinted in Table II.

Grindley and Slater (1915), on the other hand, state that when lysine and cystine are heated in the presence of carbohydrates (quantity not given) 4.7 per cent of the lysine nitrogen and 6.3 per cent of the cystine nitrogen remain in the humin fractions. The loss of 6.3 per cent of the cystine nitrogen would in all Van Slyke analyses be entirely negligible, excepting in the analysis of keratin material. This is shown by reference to Table V, the cystine content of the protein being taken from Van Slyke's (1911) data.

As to the adsorption of 4.7 per cent of the lysine N by the humin, Osborne (1915) showed that when an *equal* weight of carbohydrate was added to a protein no such adsorption was detectable. They find from 12.09 to 12.35 per cent of lysine in lactalbumin when hydrolyzed alone and 12.54 per cent in lactalbumin hydrolyzed in the presence of an equal weight of dextrose. *If 4.7 per cent of the lysine had been adsorbed by the humin the latter figure should*

have been only 11.67 per cent. In any case, however, the differences are within the 0.63 per cent given (by Van Slyke, 1911) as the "average difference" between duplicate determinations.

It seemed well, however, to make a complete analysis of a protein hydrolyzed in the presence of a large quantity of carbohydrate. Two separate portions of approximately 3 gm. of fibrin and 9 gm. of Swedish filter paper were hydrolyzed on an electric hot plate with 100 cc. of 1.115 sp. gr. HCl for 48 hours, and at the same time two flasks containing an equal amount of fibrin and acid but no carbohydrate were hydrolyzed on the same hot plate. The resulting solutions were analyzed according to Van Slyke (1911, 1912, a) using the minor modifications (as regards dilution, etc.) that I have reported previously (1913).¹ The bases were precipitated from a volume of 200 cc., were filtered off after cooling to nearly 0°, and washed with washing solution also cooled to near 0°. The figures are not corrected for the solubility of the basic phosphotungstates. The comparative analyses are shown in Table VI.

It will be seen that the most notable change occurs in the humin nitrogen. Table VII shows the differences between the duplicate determinations, the differences apparently due to the addition of the 9 gm. of carbohydrate to 3 gm. of fibrin, as well as the differences between lactalbumin hydrolyzed alone and in the presence of an equal weight of dextrose (data of Osborne, 1915). Van Slyke's (1911) "maximum difference" and "aver-

¹ In making these analyses I overlooked the recent modification of Van Slyke (1915) and liberated the bases with baryta as in the earlier directions.

age difference" to be expected between duplicate determinations are also included in the table for reference.

By a study of Table VII it will be seen that the differences between the analyses of those proteins hydrolyzed alone and in the presence of carbohydrate material not to exceed three times

the weight of the protein are, in the case of most of the fractions, within the maximum allowed by Van Slyke for experimental error. The only differences which are *certainly* greater than experimental error are those of humin nitrogen and amino nitrogen in the filtrate from the bases. It seems probable, however, that there is a significant loss in the arginine N and a gain in the non-amino N in the filtrate from the bases. As regards the other observed changes, I am inclined to regard them as due to experimental error, although the change in lysine N due to hydrolysis in the presence of three times the protein's weight of carbohydrate may be significant.

The data already given in Tables IV, VI, and VII indicate that an exact determination of the chemical groups in proteins

† The figure in brackets represents the second greatest difference between duplicates observed by Van Slyke (1911).

by Van Slyke's method cannot be expected when an amount of carbohydrate equal to three times the weight of the protein is present. To make this point doubly sure, however, the following experiment was carried out.

The filtrates from the humin determinations of 3 gm. of fibrin, hydrolyzed alone and in the presence of 3 gm. of soluble starch were evaporated to approximately 35 cc. volume *in vacuo*, a large excess of concentrated hydrochloric acid was added, and the solution again evaporated *in vacuo* to about 35 cc. This solution was washed out into the hydrolyzing flasks with 1.115 sp. gr. HCl so that the total volume was 75 to 100 cc. 3 gm. of soluble starch were added to the residue, which had been previously hydrolyzed in the presence of starch, and nothing was added to the residue which had been hydrolyzed alone. The contents of the flasks were boiled again for 48 hours, and ammonia N and humin N determined on the resulting solutions as usual. The data are given in Table VIII. It will be seen that there is a marked gain of ammonia nitrogen which does not differ greatly in the case of the fibrin + carbohydrate from that of the fibrin alone. The differences are believed to be within experimental error. Van Slyke (1912, b) has observed this increase of ammonia

TABLE VIII.

The Ammonia N and Humin N Formed from the Filtrates from the Humin of 3 Gm of Fibrin + 3 Gm of Starch when Boiled a Second Time in the Presence of 3 Gm of Starch, Compared with a Second Boiling (without Carbohydrate Addition) of the Filtrate from the Humin of 3 Gm of Fibrin Hydrolyzed Alone.

N due to prolonged hydrolysis and in certain unpublished work carried out before Van Slyke's results were published I made a similar observation.² In Table VIII there is an increase of 18.30 per cent of the original ammonia nitrogen due to a further hydrolysis. The origin of this ammonia, and the length of time the increase will continue are now being studied at this Experiment Station.

The humin nitrogen increases only 6.79 per cent of the original humin N on further hydrolysis when no carbohydrate is added, and 21.32 per cent on the addition of more carbohydrate (actually 46.04 per cent increase calculated on the original fibrin + no carbohydrate). This would indicate that the increase of 115.8 per cent of humin N in the first hydrolysis was caused by a chemical reaction, augmented by adsorption or occlusion of other amino-acids by the carbohydrate humin. The further increase of 46.04 per cent of the humin nitrogen on a second hydrolysis is almost conclusive proof of such adsorption, absorption, or occlusion.

A Comparison of Van Slyke's (1911) Analysis of Fibrin with the Data of Table VI.—When my analysis of fibrin was compared

² The following results were obtained in February and March, 1911, at the Station for Experimental Evolution, Carnegie Institution of Washington.

the last figure being 15.0 per cent increase over 48 hours' hydrolysis.

Van Slyke's results were announced before the work could be repeated and confirmed on other proteins, and inasmuch as his data were in substantial agreement with my own the investigation was discontinued.

with the analysis of Van Slyke (1911), as in Table IX, there is observed a very close agreement in all of the figures excepting in the ammonia N and arginine N. The difference in the ammonia figures is undoubtedly due to the fact that Van Slyke hydrolyzed his fibrin for a shorter period than 48 hours.³

* Van Slyke's figures are those which were not corrected for solubility of the bases. These were taken, instead of the corrected values, so that they would be directly comparable with my data.

B. Hydrolysis of Proteins in the Presence of Aldehydes.

In the preceding paper (Gortner and Blish, 1915) the following statement was made:

"When carbohydrates are boiled with mineral acids, a small amount of furfural is formed and it seems highly probable that the reaction involved in humin formation is the condensation of tryptophane with an aldehyde. Miss Homer (1913, a) has prepared condensation products of tryptophane with various aldehydes and states: 'Indole derivatives by virtue of the -NH group in the nucleus will react with formaldehyde and trioxymethylene in the presence of a condensing agent to form substances of intense color and marked insolubility in ordinary solvents other than concentrated mineral acids.'"

It is well known that aldehydes produce certain color reactions when added to protein material, and that addition products and condensation

³ Van Slyke does not mention the length of hydrolysis for fibrin but in other data in the same paper he speaks of hydrolyzing for 28 hours.

products can be obtained between aldehydes and certain of the amino-acids. For example, the Adamkiewicz reaction or glyoxylic reaction (Hopkins and Cole, 1901) of proteins appears to be due to the presence of nascent formaldehyde acting upon tryptophane.

Reichl's (1890-91) test for tryptophane in proteins depends upon a color reaction produced in the presence of benzaldehyde, 50 per cent sulfuric acid, and some oxidizing agent (ferric chloride).

The Ehrlich-Neubauer (1903) and Rohde (1905) test for tryptophane is dependent upon a coloration produced by *p*-dimethylaminobenzaldehyde, and Herzfeld (1913) has utilized this coloration to elaborate a colorimetric method for the estimation of tryptophane in the tryptic digest of proteins.

Rohde (1905) finds that the aliphatic aldehydes, formic, acetic, propionic, or butyric, do not give color reactions with proteins, that furfural or citral give only a yellowish color, while all aromatic aldehydes produce more or less brilliant colors, varying from red to blue or green, depending upon the aromatic aldehyde used. He, likewise, finds that gelatin, carefully purified, produces no color with aromatic aldehydes, and that tyrosine + gelatin does not give a color. He therefore concludes that the color is produced only in the presence of tryptophane.

Steensma (1906) extends Rohde's work by testing the reaction of other aldehydes and by showing the color changes which may be induced by a trace of an oxidizing agent (nitrous acid).

It would seem that all of the color tests referred to above are produced by reactions which involve the $-NH$ group of tryptophane instead of the aliphatic amino group. Miss Homer (1913, a and b, and 1915) finds that, when a condensing agent is present, formaldehyde and trioxymethylene react with tryptophane to form "substances of intense color and marked insolubility in ordinary solvents." Of course this is merely the Adamkiewicz reaction, or the glyoxylic reaction, carried further, so that the colored product is actually isolated.

The aliphatic amino group, likewise, reacts readily with aldehydes. Miss Homer (1913, a) prepared a number of condensation products of indole derivations with aldehydes, tryptophane being one of the indole compounds studied. She was able to isolate a colorless, crystalline compound of tryptophane and formaldehyde, the condensation taking place on the aliphatic amino group of the tryptophane. It seems very probable that similar crystalline condensation products could be prepared from all, or almost all, of the amino-acids, not only with formaldehyde, but with other aldehydes. That such a reaction takes place very readily between amino-acids and formaldehyde in neutral

solution is evinced by the well known method of Sørensen (1908), where formaldehyde is used to titrate the free amino-acids in a solution, the reaction taking place being

Trillat (1892), Blum (1896), Benedicenti (1897), Schwarz (1900), and Treves and Salomone (1908) studied a similar type of reaction in which the amino-acids are replaced by an entire protein molecule. They find that a chemical combination takes place between aldehydes and proteins, presumably on the aliphatic amino group, to form aldehyde-proteins. These compounds possess properties which are widely different from the parent protein; for example, aldehyde-albumin formed from egg-white is not coagulated on boiling and is not attacked by trypsin. It is claimed that all of the aldehyde (formaldehyde) can be removed from the aldehyde-protein by steam distillation. If this is actually the case, it would indicate a somewhat loose combination, and would also indicate that the $-\text{NH}$ group of tryptophane and the hydroxyl group of tyrosine were not involved in the reaction. Additional data are desirable on this point.

Ultimate analyses of aldehyde-proteins (Schwarz, 1900) and of indole and skatole condensation products with trioxymethylene (Homer 1913, a) are on record, but I have been unable to find any literature bearing on the subject of the *nitrogen distribution* either in pure proteins or with individual amino-acids, after heating with aldehydes in the presence of a condensing agent. It seemed advisable, therefore, to make some experiments in which proteins were hydrolyzed in the presence of aldehydes.

The results which will be reported in the following pages are unavoidably incomplete,⁴ and serve mainly to show that there is here a field worthy of more complete investigation. The data which have been collected to date are here presented, and active work in this field will be continued at once. Unless some one has already begun a study of the effect of the presence of aldehydes on the nitrogen distribution in the hydrolysates of proteins and

⁴ On Aug. 1, 1916, the writer transferred from the Division of Soils to the Division of Agricultural Bio-Chemistry, in charge of the Section of Biochemical Research.

protein materials, I should like to reserve this field for the present.

Hydrolysis of Fibrin in the Presence of Furfural.—As is noted above, Gortner and Blish (1915) postulated that perhaps the reactivity of the carbohydrate was due to furfural. The following experiments were therefore made.

3 gm. of fibrin were hydrolyzed by boiling for 48 hours with 75 cc. 1.115 sp. gr. HCl in the presence of 0.25, 0.50, 1.0, and 5.0 cc. of freshly distilled furfural.

On adding the furfural to the HCl + fibrin, an intense red-violet coloration formed at once in the cold. The flakes of fibrin rapidly darkened in the cold solution so that within 2 or 3 minutes they were jet-black.

On an attempt to heat the mixture of 5 cc. of furfural + 75 cc. HCl + 3 gm. of fibrin a vigorous reaction took place as soon as the solution began to get warm, followed almost at once by a violent explosion which shattered the flask. The reaction began in much the same manner that sucrose and concentrated sulfuric acid react to form charcoal.

In the other experiments where smaller quantities of furfural were used, successful hydrolysis was obtained, although the large amount of humin caused trouble in several instances in the flasks containing 1 cc. of furfural. In two instances hydrolysates containing 1 cc. of furfural were lost because of minor explosions, throwing a part of the contents out of the flasks. The humin in all instances was jet-black and granular, washed quite readily, and was very bulky, that from the hydrolysate containing 1 cc. of furfural almost filling a 15 cm. filter paper. In all experiments, except that where only 0.25 cc. of furfural was used, the hydrolysate was clear, excepting for the suspended solid mass of humin; *i.e., all color was insoluble.* The experimental data are shown in Table X.

It will be seen that we have here much the same type of reaction as that shown by varying the amount of carbohydrate (Table IV); *i.e., a sudden initial rise in the humin nitrogen, followed by a slow increase which shows no sign of soon reaching a maximum.* This would indicate a chemical combination followed by adsorption or occlusion. Indeed, it seems to me to

be extremely probable that the humin formed from carbohydrates is actually formed from furfural, which is in turn formed from carbohydrates. The polymerization (?) of furfural to humin by strong HCl takes place very rapidly, and, when a very considerable amount of furfural is present, may assume explosive violence.

In order to arrive at some idea as to the proportions of humin formed from furfural, and from carbohydrate material, I boiled 1 cc. of furfural (1.165 gm.) with 100 cc. of 1.115 sp. gr. HCl for 18 hours, filtered the resulting humin on a weighed Gooch crucible, washed with warm water, dried at 105°, and weighed; 0.8902 gm. of black insoluble "humin" was obtained or 76.40 per cent of the original furfural. From 3 gm. of Swedish filter paper treated in a similar manner only 0.4650 gm. humin was obtained or 15.50 per cent of the original carbohydrate.

It is obvious from the above work that carbohydrates and furfural behave in the same manner when added in a protein hydrolysis. Both chemical and physical reactions take place and the increase in the nitrogen content of the humin cannot be definitely assigned to any amino-acid or groups of amino-acids.

Hydrolysis of Fibrin in the Presence of Benzaldehyde.—The preceding experiment was repeated, replacing the furfural with benzaldehyde using 0.5, 1.0, 2.0, and 4.0 cc., respectively. Benzoic acid crystals were present in all flasks at the end of the hydrolysis. Free benzaldehyde likewise distilled off in all experiments, except that where 0.5 cc. was added, and in this instance there was still a detectable odor.

In the case of 1, 2, and 4 cc. of benzaldehyde, the humin "balled" together into a cake which was pasty when hot, but hard when cold. The liquid in the flasks had no trace of black color, except in that where only 0.5 cc. of benzaldehyde was added. In all of the others the liquid was light yellow during the last half of the hydrolysis. This is a notable exception to the usual course of hydrolysis (compare also the furfural, which acted in a similar manner).

After the first experiments had been completed, it was found desirable to separate the humin into two fractions, "acid-insoluble" and "acid-soluble." The acid-insoluble humin was obtained in two additional experiments by diluting the hydrolysate, filtering off the insoluble humin, and washing it free from acid. The filtrate from the acid-insoluble humin was then concentrated as usual, to get rid of the excess of HCl, calcium hydroxide added, and the ammonia distilled off. The "acid-soluble" humin was adsorbed by or combined with the lime, and was determined in the usual manner for the humin determination.

In those experiments where no benzaldehyde was added, the filtrate from the "acid-insoluble" humin was jet-black, and, as is shown in the table, contained nearly 50 per cent of the normal humin N. The "acid-soluble" humin from the benzaldehyde experiments formed a light tan colored precipitate, very small in amount as compared with the usual humin precipitate. The data are shown in Table XI.

It will be noted that decidedly different results are obtained with benzaldehyde from those obtained in the presence of carbohydrates or furfural. The reactions here appear to be wholly chemical. The ammonia nitrogen is probably not significantly altered by the amounts of benzaldehyde used, although, as will be shown later, there is possibly some deamination with the larger quantities of benzaldehyde.

The humin nitrogen rises rapidly to a maximum of approximately double the amount of the humin N produced in the ordinary hydrolysis. There is some indication that the maximum amount of humin nitrogen is not reached when the larger quantities of benzaldehyde are present. This is almost certainly the case when the benzaldehyde is replaced by formaldehyde (see later). The major part (92 to 95 per cent) of the humin nitrogen formed

TABLE XI.

in the presence of benzaldehyde is insoluble in acids, while in the hydrolysate of fibrin alone, approximately 45 per cent of the humin nitrogen was acid-soluble, forming a jet-black solution in the diluted hydrochloric acid, but being completely adsorbed by or combining with the lime in the ammonia determination. Just what significance lies in the "acid-insoluble" and "acid-soluble" figures will be made a subject for further investigation.

Hydrolysis of Fibrin in the Presence of Formaldehyde.—The experiments with furfural and benzaldehyde were repeated, using instead 0.5, 1.0, 2.0, and 4.0 cc. of a 40 per cent solution of formaldehyde. The figures obtained for those experiments where 0.5 and 4.0 cc. were used, were so unexpected that they were repeated at a later date and, to my surprise, were confirmed. The data obtained are shown in Table XII.

It will be seen that here, again, we are dealing with a number of chemical reactions. The ammonia nitrogen falls significantly when small quantities of formaldehyde are added, but rises very rapidly when larger quantities are present. This rise must be due to deamination, but with the data at hand it is impossible to obtain any definite idea of the reactions involved.

In all cases the filtrate from the acid-insoluble humin was dark red-brown, in decided contrast to that from the experiments where furfural or benzaldehyde was used. Only small quantities of

† Data of Table XI.

acid-insoluble humin were obtained from those experiments where 1 cc. or more of formaldehyde was present, and this humin lacked the intense black color normally present, being decidedly brown. The acid filtrate, on concentration, yielded a red-brown resin, which was easily soluble in hot water, forming a red-brown solution. The filtrate from the acid-soluble humin, in the experiment where 4 cc. of formaldehyde were used, was *dark red* but clear. The red color diminished in intensity down to 0.5 cc. of formaldehyde, where the color was but slightly deeper yellow than normal.

With the data at hand it is impossible to determine what reactions are involved in the initial gain of approximately 30 per cent in acid-insoluble nitrogen in the case where 0.5 cc. of HCHO was added, followed almost at once by a rapid fall, amounting to a loss of nearly 70 per cent of the insoluble humin when 1.0 cc. of HCHO was added. The insoluble humin N which was lost appears to be recovered in the "acid-soluble" humin N but it is impossible to state whether this is actually the case or whether it remains in the filtrate from the humin.

The Nitrogen Distribution of Tyrosine and Tryptophane when

Boiled with Benzaldehyde and Formaldehyde.—In view of the peculiar results obtained by hydrolyzing fibrin in the presence of benzaldehyde and formaldehyde, it was thought advisable to test out the effect of these aldehydes on individual amino-acids. The only amino-acids which were available at this time were tryptophane and tyrosine. Both of these compounds are of special interest. Tryptophane is important in view of my belief (Gortner and Blish, 1915) that a very considerable portion of the humin nitrogen of *protein* hydrolysis has its origin in the tryptophane molecule.

Tyrosine should be of special importance in a study involving formaldehyde and hydrochloric acid. It has long been known that phenols will react with formaldehyde to form various products depending upon the conditions under which the reaction is carried out⁵ and it seemed very probable that tyrosine, because of its hydroxyl group, would form a resin with formaldehyde when heated in the presence of strong hydrochloric acid.

When formaldehyde was added to tryptophane + HCl, a light yellow-gray precipitate separated in the cold. This is probably Miss Homer's (1913, a) crystalline condensation product, although the granules showed no crystal form under a magnification of 600 diameters. On warming, the solution rapidly became black and a very considerable amount of black insoluble humin separated. The acid filtrate from the insoluble humin was in every instance deep red. This red color remained in the "soluble humin" fraction, the filtrate from the soluble humin having the usual yellowish color.

Adding benzaldehyde to the tryptophane + HCl and warming produced an intense black coloration. Within a short time after boiling began, however, the insoluble humin "balled" together, leaving the liquid light yellow. The small amount of "soluble humin" was snow white, and was probably only lime.

Tyrosine + benzaldehyde + HCl, on heating, did not develop a black color throughout the solution, the only blackening which occurred seemed to be in the benzaldehyde floating upon the surface of the acid. This gradually darkened so as to be almost

⁵ For the literature and a discussion of these reactions, see Baekeland (1909, a and b).

 ‡ Calculated.

black, and on cooling, solidified to a black mass. The filtrate from the acid-insoluble humin was bright orange.

On boiling tyrosine with formaldehyde + HCl, no black coloration appeared. The solution darkened slightly, however, a red-yellow coloration being produced. On evaporating off the HCl, a red-yellow resin was left, which easily dissolved in hot water. The calcium precipitate (soluble humin) was light yellow, gelatinous, and filtered slowly. The filtrate from the soluble humin was bright orange, the color deepening with increasing amounts of formaldehyde.

The experimental data are given in Table XIII. It is useless to discuss the individual experiments until additional data are obtained. Several notable differences are, however, apparent.

1. The ammonia determinations show that deamination of both amino-acids takes place under the influence of either aldehyde, and that this deamination occurs somewhat more readily in the case of tryptophane.

2. Heating with HCl in the presence of benzaldehyde causes a large percentage of the nitrogen of both tryptophane and tyrosine to remain in the "acid-insoluble" humin.

3. Heating with HCl in the presence of formaldehyde produces a very considerable amount of acid-insoluble humin in the case of tryptophane and no acid-insoluble humin in the case of tyrosine. A very considerable proportion of the tyrosine nitrogen is retained in the acid-soluble humin.

4. Increasing the amount of formaldehyde used *decreases* the yield of "humin" nitrogen formed from tyrosine, the nitrogen returning to a form in which it is not precipitated by calcium hydroxide.

SUMMARY.

1. The figures for ammonia N in a protein hydrolysate are not significantly altered when the hydrolysis is carried out in the presence of a quantity of carbohydrate equal to three times the weight of the protein material.

2. Humin nitrogen is greatly increased by the addition of carbohydrate material. This increase is probably due both to chemical and physical causes.

3. Tryptophane cannot be accurately estimated by hydrolyzing proteins in the presence of carbohydrates.

4. If the weight of carbohydrate material present during protein hydrolysis greatly exceeds the amount of protein, an accurate nitrogen distribution, by Van Slyke's method, cannot be obtained.

5. Attention is called to the fact that, when nitrogenous compounds other than proteins are present in a hydrolysate, no reliance can be placed upon the figures obtained in any of the fractions, as representing actual amino-acids. Such data should not be compared with those obtained by the analysis of pure proteins.

6. When fibrin is hydrolyzed in the presence of furfural, the humin nitrogen is greatly increased, but it seems probable that this increase is due, not only to a chemical reaction, in which certain amino-acids combine with furfural, but also to adsorption or occlusion of other amino-acid nitrogen by the humin.

7. When furfural is boiled with strong hydrochloric acid approximately 75 per cent by weight is converted into a black insoluble mass. It is suggested that perhaps the humin, formed from carbohydrates by boiling with hydrochloric acid, is actually formed from furfural, which is in turn formed from the carbohydrate.

8. When fibrin is hydrolyzed in the presence of benzaldehyde, the humin nitrogen rises rapidly to a maximum of approximately double the amount produced by ordinary hydrolysis. This humin nitrogen is nearly all "acid-insoluble." The reaction here appears to be wholly chemical. The ammonia nitrogen is not significantly altered, although there is evidence that some deamination takes place.

9. When fibrin is hydrolyzed in the presence of formaldehyde, there is an initial gain of "acid-insoluble" humin where small amounts of formaldehyde are used, but a large loss when greater quantities are present. The total humin nitrogen (acid-insoluble + acid-soluble humin) is fairly uniform for all quantities of formaldehyde, and shows an increase of approximately 150 per cent of the normal humin nitrogen. Deamination occurs in the presence of the larger quantities of formaldehyde.

10. Both tryptophane and tyrosine yield a very considerable

proportion of "acid-insoluble" humin nitrogen, when boiled with hydrochloric acid in the presence of benzaldehyde.

11. When tryptophane is boiled with formaldehyde, in the presence of hydrochloric acid, a very considerable part of the nitrogen is retained in the acid-insoluble humin. This is in decided contrast to the behavior of tyrosine, where no acid-insoluble humin is formed, but where a greater or less percentage of the nitrogen is retained in the "acid-soluble" humin, the amount retained depending upon the quantity of formaldehyde present. Some deamination occurs in both amino-acids, when heated with either aldehyde, in the presence of hydrochloric acid.

The work is being continued along lines suggested by these results.

THE URIC ACID SOLVENT POWER OF NORMAL URINE.

By HOWARD D. HASKINS.

(From the Department of Biochemistry, Medical School, University of Oregon, Portland.)

(Received for publication, June 27, 1916.)

Very little work has been done to determine the amount of uric acid which urines from normal individuals can take up by being shaken with pure uric acid. The only investigations of consequence are those of Hindhede¹ and Blatherwick.²

Certain researches reported elsewhere by the author³ involved the determination of the power of normal urines to dissolve uric acid, and it may be of interest to report the findings in full in this paper. We had hoped to discover all the main factors on which the uric acid dissolving power of urines depends, so as to be able on the basis of certain data to foretell approximately how much uric acid would be dissolved by a particular urine. In this we were doomed to disappointment. The only factors which we have proved to play a definite part are the acidity of the urine and its concentration. Some urines that are slightly acid and all those that are neutral or alkaline dissolve extra uric acid. On the other hand the solvent power of urines of ordinary concentration is distinctly increased by dilution. For instance, the total uric acid dissolved by 100 cc. of urine after being diluted with 300 cc. of distilled water may be even twice as much as that dissolved by 100 cc. of undiluted urine. This will explain why we have reported the dilute urines in a separate table.

Methods.

In determining solvent power the urines were first warmed to 37°C., and after adding an excess of pure uric acid the flasks were kept in a bath at 37°C. for exactly 20 minutes, the urines being shaken frequently so that undissolved uric acid was constantly in suspension. They were filtered immediately after removal from the bath, and the uric acid estimation was made on the filtrates. A longer period of warming was not found to give superior results. Body temperature was chosen so as to be comparable to the physiological condition of urine lying in the bladder.

The uric acid estimations were made by the usual method; *i.e.*, by precipitation by means of ammonium hydroxide in the presence of a considerable concentration of ammonium sulfate, filtration, and subsequent solution of the precipitate in hot dilute sulfuric acid and its estimation by titration with potassium permanganate.

The hydrogen ion concentration or acidity of the urines was determined by the method of Henderson and Palmer.⁴

The figures in the tables for acidity of the urines are the "hydrogen exponents" (P_H); these are (negative) logarithmic figures corresponding to the true hydrogen ion concentrations. The smaller the figure the greater the acidity. Neutrality is 7.0. The reaction of normal urines which we have examined ranges from a distinctly acid urine, 5.0, to a lightly alkaline urine, 7.4.

Hindhede's method of determining solvent power of urines was found to be quite unsatisfactory. Our work was carried out independently, being uninfluenced by the investigations of others. It is necessary to say a word in regard to Blatherwick's method. It is quite possible that by his method of shaking with uric acid for 2 hours at room temperature somewhat different results would be obtained than by our method of shaking for 20 minutes at body temperature. We would, therefore, warn against comparing the results by the two methods.

Tables I and II give the results of the experimental work. The figures for uric acid are given as mg. in 100 cc. of urine. "Uric acid content" means the amount present in the urine as passed. "Total uric acid" means the amount present in the filtrate after shaking with uric acid. The difference between these two is the "uric acid dissolved." This last is the index of the solvent power of the urine.

From a study of the tables it will be seen that many acid urines (5.8 to 6.9 acidity) have the power to take up additional uric acid, the amount being greater than distilled water will dissolve; namely, 8.4 mg. per 100 cc. The uric acid content of many of these urines (see Table II) is as great as occurs during an ordinary high excretion of uric acid (50 to 70 mg.). Many urines

⁴ Henderson, L. J., and Palmer, W. W., *J. Biol. Chem.*, 1912-13, xiii, 393.

of an acidity between 5.8 and 6.3, which were tested, dissolved no extra uric acid and therefore were not included in the tables. It was most surprising to find solvent power in *any* urines of that range of acidity. The result with the urine of 5.9 acidity (No. 140) was quite remarkable. In the case of urines of acidity 6.4 to 7.4 almost every one that we have tested showed uric acid solvent power.

It will be observed that in a general way the amount of uric acid dissolved increases as the acidity of the urine decreases (*i.e.*, as the acidity figure becomes greater). Disregarding a few of the exceptionally high estimations and a number of the exceptionally low ones, the extremes of the amounts of uric acid dissolved for various ranges of acidity are about as follows:

Acidity.	Uric acid dissolved.
5.8 to 6.35	5 to 40 mg. (both dilute and less dilute urines).
6.4 " 6.55	25 " 60 " " " " " " "
6.6 " 6.7	40 " 100 " " " " " " "
6.75 " 6.8	50 " 115 " (dilute); up to 155 mg. (less dilute).
6.85 " 6.9	105 " 140 " " " 160 " " "
6.95 " 7.0	105 " 120 " " " 225 " " "
7.1 " 7.3	145 " 155 " " 105 to 190 " " "

It does not seem to us advisable to calculate averages for the amount dissolved by urines of the same acidity, as it would be misleading because of the wide variations in the amounts. For example, for acidity 6.8 (Table II) the figures run from 35 to 154 mg.

A number of the urines show exceptionally high solvent power as compared with others of the same acidity, notably 29 and 58 in Table I, also 91, 106, 113, and 140 in Table II.

In order to determine whether the inorganic constituents of the urine could of themselves account for the solvent power of any particular urine, 700 cc. of urine were evaporated and ashed, then the ash was redissolved in 700 cc. of distilled water. On shaking with uric acid the ash solution dissolved 39 mg. per 100 cc. while the original urine took up 40 mg. In the case of this urine at least it was probable that the uric acid was dissolved because of a reaction with disodium phosphate producing mono-

sodium phosphate and monosodium urate. This reaction occurs readily with mixtures containing only the two phosphates, these mixtures resembling urines in so far as concerns acidity and phosphate content. Urines of different acidities contain different proportions of Na_2HPO_4 and NaH_2PO_4 ; *e.g.*, a urine of acidity 6.8 contains equimolecular quantities of the two, but one of acidity 7.4 contains about four times as much Na_2HPO_4 as NaH_2PO_4 .

Solutions having different concentrations of the phosphates but having the same acidity show a power to dissolve uric acid in a ratio entirely different from that of the dilution. This has a bearing on the fact which is made apparent by a comparison of the results reported in Tables I and II; namely, that the dilute urines have a solvent power out of proportion to their concentration. The results of the experiment with phosphate mixtures are given in Table III.

TABLE III.
Solvent Action of Phosphate Mixtures.

No.	Acidity, P _H .	Uric acid dissolved, mg. per 100 cc.	Gram molecular concentration.
1	6.8	138.2	1/15
2	6.8	120.0	1/30
3	6.8	75.5	1/60
4	6.9	90.0	1/50
5	6.9	58.8	1/100
6	6.8	78.8	1/50
7	6.8	50.0	1/100
8	6.65	54.4	1/50
9	6.65	39.6	1/100

It will be seen that the solvent power is not nearly proportional to the concentration, for instance, Solution 3 is only one-fourth as concentrated as Solution 1 but dissolves more than half as much uric acid as 1. Compare also 5 with 4, 7 with 6, and 9 with 8. Similar results were obtained with urines after dilution with one and with three volumes of water (Table IV).

TABLE IV.
Solvent Action of Diluted Urines.

Dilution	Acidity, P _H .	Uric acid content	Total uric acid	Uric acid dissolved.
		Mg per 100 cc		
Urine A ..	6.8	70.0	162.8	92.8
50 per cent of A	6.8	35.0	112.4	77.4
25 " " " "	6.75	17.5	80.4	62.9
Urine B	6.4	10.8	86.0	75.2
50 per cent of B. .	6.35	5.4	53.2	47.8
25 " " " "	6.3	2.7	30.4	27.7

The solvent power of certain very dilute urines was one of the most surprising results of our investigation. One sample of urine passed as a consequence of excessive drinking of water, having a specific gravity of 1.0005 (6.6 acidity), dissolved 54.4 mg. of uric acid per 100 cc. In the case of two other persons who drank large quantities of water the urine was of similar character. One passed 4,800 cc. in 24 hours (acidity 6.75), and 100 cc. of this dissolved 56 mg.; while the other passed 2,800 cc. (acidity 6.8), 100 cc. dissolving 114 mg. It is possible that one of the important factors involved in dilution is decrease in concentration of sodium ions. By what is called the "common ion effect" the solubility of a salt is lessened whenever another salt is present, one of whose ions is identical with an ion of the salt in question. The presence of sodium ions (*e.g.*, from NaCl) in the urine must therefore depress the solubility of monosodium urate, and the more dilute the urine the less the depression of solubility because of the smaller number of ions present. In the case of simple aqueous solutions the sodium ion effect is readily demonstrated. Monosodium urate dissolves in water so that a solution is easily obtained which contains an amount of urate equivalent to 170 mg. of uric acid in 100 cc. On the other hand solutions of four different sodium salts (each containing the same amount of sodium as a 0.3 per cent NaCl solution) dissolved only a trace of sodium urate. In solutions of potassium salts the urate dissolved quite readily.

For some reason this ion effect does not seem to be so marked in the case of urine and phosphate mixtures. The addition of

1 per cent NaCl to a phosphate mixture (acidity 6.8) diminished the uric acid dissolved from 120 mg. to 105. Also in the case of a urine which showed great solvent power (206 mg. per 100 cc.) the addition of NaCl had little effect (200 mg. dissolved). These findings seem to minimize somewhat the importance of the ion effect.

By referring to Tables I and II it will be seen that a considerable number of urines (twenty-four) show figures for "total uric acid" greater than the uric acid content of a saturated solution of sodium urate (170 mg.). Figures for total uric acid of 252, 276, 282, 291, and 343 can hardly be explained on the basis of solution occurring as the result of a reaction producing monosodium urate. There must be some other factor responsible for the apparent supersaturation. Urines passed after taking sodium bicarbonate or citrate behave in a similar manner (Table V).

TABLE V.

Solvent Action of Urine after Sodium Citrate and Bicarbonate.

Acidity, Ph.	Salt taken	Uric acid content.	Total uric acid.	Uric acid dissolved
		Mg per 100 cc.		
7 6	Bicarbonate.	13.8	296 9	283 1
7 3	"	96 6	446 6	350 0
7 3	"	105 0	360 8	255 8
7.3	Citrate.	70 5	283 9	213 4
7.3	"	129 2	313 9	184 6
7.25	"	56 0	227.2	171 2
7 25	"	72.0	222 3	150 3
7.2	Bicarbonate.	55 5	279 0	223 5
7.2	Citrate.	52 0	218 9	166 9
7 15	"	27 0	210 4	183 4
7.1	"	30 6	197 9	167 3

The most probable explanation of this apparent supersaturation is that at least part of the uric acid is in colloidal solution. Schade and Boden⁵ have shown that dilute alkalies can cause colloidal solution of uric acid at body temperature. By careful manipulation they put 500 mg. of uric acid into solution in

⁵ Schade, H., and Boden, E., *Z. physiol. Chem.*, 1913, lxxviii, 347.

40 cc. of dilute sodium hydroxide. They believe that the colloids of the blood stabilize colloidal uric acid, and also that colloids in the urine can exert the same action so that uric acid can exist in it in colloidal form. It is not necessarily true that *all* of the uric acid taken up by any of our urines was put into colloidal solution, part of that dissolved may have become monosodium urate. We noticed that the precipitate from some urines after adding ammonium hydroxide was gelatinous, quite unlike the usual ammonium urate precipitate; these may have held uric acid in colloidal solution. No record was made of the particular urines that behaved in this manner.

Bechhold⁶ has confirmed the existence of colloidal solutions of uric acid by the use of the ultra filter, the solution remaining on the filter becoming very much more concentrated in uric acid because the filter holds back the colloidal particles.

SUMMARY.

1. When shaken with uric acid for 20 minutes at 37°C. many urines that are slightly acid and all that are neutral or alkaline take up extra uric acid.

2. The less acid the urine the more uric acid, as a rule, it will dissolve.

3. Dilute urines when considered in proportion to their concentration show much greater solvent power than less dilute urines.

4. Some urines dissolve so much uric acid that they come to contain more uric acid than is present in a saturated solution of monosodium urate. In all probability in these cases at least part of the uric acid is in colloidal solution.

CELL PENETRATION BY ACIDS.

II. FURTHER OBSERVATIONS ON THE BLUE PIGMENT OF CHROMODORIS ZEBRA.

By W. J. CROZIER.

Contributions from the Bermuda Biological Station for Research, No. 48.

(Received for publication, June 26, 1916.)

I. The blue substance occurring in the tissues of the large nudibranch *Chromodoris zebra* Heilprin has been employed as an intracellular indicator for acids, which on penetrating the tissues cause the material to become pink (Crozier, 1916). This paper records some further observations with reference to the action of the pigment as an indicator and to its participation in the natural color variations of *Chromodoris*.

It was at first considered not impossible that more than one substance might be concerned in the color change produced by acids. Smallwood (1910, p. 139) states that the five or six white conical elevations on the posterior border of the mantle of *Chromodoris* turn pink when treated with nitric acid; this statement, however, certainly involves an error, because the action of acids does not in any way affect the color of the creamy white contents of these glandular organs. Smallwood (unaware of the nature of the blue substance) was probably misled by the diffusion of pigment from neighboring portions of the integument, or by the pink hue assumed in pigment-bearing cells external to the body of these white glands.

It can be stated quite definitely that the blue substance is the only indicator involved, but its reactions are sufficiently complicated to require some attention. It would be of interest, in this connection, to examine the apparently similar blue pigments of other species of *Chromodoris*. According to Eliot's description (1913, p. 29, pl. II, fig. 9) the Japanese *Chromodoris marenzelleri* Bergh is colored in such a way as to suggest a skin pigment allied to that of *C. zebra*, as is also the case with some Pacific coast species (Cockerell, 1901).

II. The blue pigment also occurs dissolved in the blood of *Chromodoris*. The blood pigment in its reactions to alkalies and acids

is identical with that obtained from the cells of the foot and general integument. The absorption spectra are likewise the same, a single band being present, which in neutral solutions centers at about $621 \mu\mu$ (Crozier, 1914). Blood obtained by means of a syringe in such a way as to be kept from contact with air is of a deep blue, almost violet, color by reflected light, reddish purple by transmitted light. The reaction of blood obtained from the auricle was estimated from a number of analyses to be about $p_H = 7.4$ ($20^\circ\text{C}.$), the procedure of Rowntree, Marriott, and Levy (1915) being used for this purpose.

Qualitative tests indicate the presence of manganese in the blood and in partially purified pigment extracts, but I am unable to say whether or not manganese forms a constituent of the pigment substance.

III. Undiluted blood and aqueous solutions of the pigment obtained from the integument were allowed to stand (a) in open vessels and (b) in tightly stoppered bottles; some of the latter contained air while others were completely filled with fluid. At $27^\circ\text{C}.$ the pigment not in contact with air was rapidly decolorized; it was determined that the presence of pieces of tissue accelerated the decolorization. The reduction was slower at 20° than at 27° . In bottles holding air above the pigment solution the upper layer remained blue for some time, but ultimately was completely decolorized; in this case the blue color could be regenerated several times by shaking. The admission of fresh air caused these solutions again to become blue, provided they had not stood too long. The pigment solutions contained in open vessels were also decolorized after the formation of a bacterial film.

The addition of neutral H_2O_2 immediately produced a permanent intense blue coloration, or a violet tint showing blue fluorescence. This color was much more intense than could be produced by long shaking with air.

During the progress of decolorization there was never any indication of a pink stage. The color change with acids is therefore not a reduction.

Extracts of the pigment made with boiling water and subsequently preserved in closed vessels were not reduced, nor was there any evidence of reduction when the extraction was made with boiling water in a flask stoppered with cotton wool. Ex-

tracts prepared in the cold were not reduced in the presence of formaldehyde, CHCl_3 , xylol, acetone, or pyridine. Numerous experiments were made by adding to solutions of the blue pigment, sterilized with CHCl_3 , portions of the body of *Chromodoris* either whole or ground with sand. No reduction was obtained in this way even when the tests were carried out in tightly closed bottles containing no free air. Negative results were likewise obtained with the liver of fishes, which yields, according to Harris and Creighton (1915), a non-specific reductase rapidly affecting hemoglobin.

The reduction of this *Chromodoris* pigment seems, therefore, to be strictly comparable to that (oxyhemocyanin) found by Alsberg (1915) in the case of *Limulus*. The reduction is not due to enzymes, but to the action of putrefactive microorganisms. If to an aqueous extract of the pigment that has been sterilized by boiling there be added a similar solution that has become reduced, the inoculated flask is likewise slowly decolorized. When allowed to stand too long, the blue color cannot be restored even with H_2O_2 , indicating that the blue substance has been destroyed.

Reduction of the blue material by direct chemical means is not easily effected. It is not decolorized by boiling, either alone or with acid, and it is only slowly reduced with zinc dust and acid. In the neutral or slightly alkaline condition the blue pigment is partially reduced to a greenish tint by Stoke's reagent, but it is not completely decolorized. Acid solutions are not reduced by Stoke's reagent. These tests with freshly prepared Stoke's reagent were checked spectroscopically.

Whether or not the blue pigment is concerned in respiration cannot as yet be decided, but its behavior certainly suggests that it may serve as an oxygen carrier. There is reason to believe that the metabolism of sluggish marine invertebrates, such as *Chromodoris*, is not of a rapid type (Vernon, 1895) and the difficulty with which the pigment seems to be reduced may thus be no real objection to its fulfilling a respiratory function. Some experiments made to test this question have not given definite results.

The method used in my previous work of handling the pieces of tissue has one advantage not mentioned in my first paper. In pressing the tissue gently between filter paper before submitting it to the action of acid, any blood pigment held in lacunar peripheral blood spaces is likely to be removed. Fortunately, it is

possible to make a decisive test showing the absence of errors from this source. Some *Chromodoris* individuals show a pure white at the edge of the mantle, although their blood is blue, as is also the surface of the foot and other portions of the skin. Pieces of this white skin tissue do not turn pink with acid, even when first treated with H_2O_2 to oxidize any blood pigment present.

IV. Several of the factors involved in determining variations in the blue coloration of this animal may be distinguished: the presence or absence of the pigment in the integument, the details of its local distribution, the extent to which it is oxidized, the proportion of the pigment which is firmly bound by the cell protoplasm as compared with that present in solution, and the reaction of the fluid locally associated with the dissolved form of the pigment. The last two factors enumerated are the most important from the standpoint of the use of the blue pigment as an intracellular indicator. It should also be stated that the oxidized condition of the pigment is the only one which is turned pink by acids; if acid is added to a reduced solution, the solution remains colorless, becoming pink only when shaken with air or treated with H_2O_2 .

These complicating factors are important in determining variations found in the acid penetration of mantle tissue from variously pigmented individuals; they are probably as much concerned at least as is the variable judgment of the observer, which I at first believed mainly responsible. As just stated, the cells of the blue integument appear to contain the pigment in two conditions: (a) a relatively free (dissolved) state, and (b) bound by the cell protoplasm in a firm combination which, as previously noted in the case of the dorsal skin, is affected only by strong acids. When pieces of the mantle are immersed in weak acid solution the pink hue may disappear after a time, leaving the tissue blue; this is due to the fact that only the dissolved (acid-sensitive) portion of the pigment is diffusible. In working at low temperatures (15°) a serious source of confusion may arise here, since the outward diffusion of pigment is frequently more rapid than the inward progress of the acid. This difficulty is, however, practically absent in freshly collected animals. With the object of following the changes in pigmentation I have studied animals maintained in the laboratory for 3 to 4 months without food, and I

am convinced that in these individuals the conditions as regards the blue pigment are materially altered from those normally obtaining. There is an increase in the relative amount of pigment not lost by diffusion into distilled water or acid, and the diffusible portion of the pigment is more *quickly* lost to a surrounding solution. The penetration time of all acids tested is much less than in freshly collected animals.

In discussing the results obtained by observing the comparative penetration speed of acids (Crozier, 1916), two circumstances were not dealt with which may be mentioned here. One is the possibility that the tissue does not remain inert when exposed to the action of acid; but is (in a sense) stimulated to oppose the entrance of the foreign material; the nature of this possible effect may be such as to involve the partial coagulation of the cell substance and an alteration in the relations of the internal pigment. Closely allied to this is the second possibility; namely, that coagulation may be induced by a variable fraction of the acid, while the remainder can affect the indicator less readily when the latter is bound (?) by coagulated protein. This source of objection is removed, I believe, by the following experiment:

When pieces of tissue which have been turned pink by acid are transferred to sea water, the acid diffuses away and sea water enters. This occurs within a few minutes, usually, depending on the acid and its concentration. The pink hue is then lost, the tissue becoming greenish blue because of the sea water alkalinity. If these pieces of tissue be then placed again in acid, they become pink almost instantly. This is true even with weak acids, as 0.05 N acetic.

V. The purple state of the indicator is the one most sensitive to the addition of acids, or rather, the solutions containing it are intermediate in actual acidity between those producing the blue and those producing the pink states. The small pigment globules within the cell may in some cases be of higher acidity than obtains in other cases, or in the rest of the cell contents; as Osterhout (1913) clearly pointed out, there are many semipermeable surfaces, probably of different qualities, comprised in the structure of a single cell. This means that, even if the protoplasm of blue and purple mantle tissues were penetrated by acids with equal ease, still in measuring penetration with this indicator the lowest

CELL PENETRATION BY ACIDS.

III. DATA ON SOME ADDITIONAL ACIDS.

By W. J. CROZIER.

Contributions from the Bermuda Biological Station for Research, No. 49.

(Received for publication, June 26, 1916.)

I. Several additional acids have been used in continuing a study of the penetration of living cells by acids, the object being to discover to what extent the visible penetration of diverse acids may be used to analyze the cell surface and the effect of various conditions upon it.¹ A description of the method according to which the indicator-containing tissue of the nudibranch *Chromodoris zebra* is utilized for this purpose has been given in a previous paper (Crozier, 1916). The present experiments having been made some months subsequent to those previously recorded, dilution curves were redetermined for acids (valeric, succinic) with which it was desired to compare the ones added to the list of eighteen first studied. In Table I the first and second series

TABLE I.

Penetration Time: A = First Series of Tests (Late Summer, 1915); B = Second Series (Spring, 1916). 27°C. (See Text.)

Dilution, normal.	Valeric.		Succinic.	
	A.	B.	A.	B.
<i>liters</i>	<i>min.</i>	<i>min.</i>	<i>min.</i>	<i>min.</i>

75	1.5	1.7		17.4
100	1.9	2.2	16.5	22.5
150	6.0	6.5		38
200	12.0	15.0	45	60
300	26.0	27.0		
400	55.0	62.0		

¹ I am indebted to Professor E. L. Mark for assistance in obtaining material for this work.

of measurements for succinic and isovaleric acids are compared; the figures represent in each instance the mean of ten or more concordant experiments. The differences to be observed are in the main due, I believe, to seasonal fluctuations in the condition of the tissue experimented upon.² The nature of this seasonal fluctuation may, however, be fairly simple; it is not improbable that the lower temperature of these animals during the winter months is responsible for the differences found. All the measurements recorded were carried out at 27°C., which corresponds pretty closely to the temperature of *Chromodoris* in summer time, while in winter their natural temperature is at times as low as 15°. The animals employed for this work were living at 19-20°, and it is not to be expected that a brief elevation to 27° would have the same effect upon them as would a long residence at that temperature. Variations in the alkalinity of the sea water may also be significant.

The acids used were *n*-caproic, maleic, and fumaric. The solutions were made up in distilled water, and (as in the previous measurements) in some instances also in rain water; in both cases the results were the same. This apparent disregard of familiar osmotic and other effects has been quite deliberate, since it is proposed to use these data as a starting point from which to begin a study of the actions of individual salts.³ Distilled water (or rain water) in the absence of acid produces, of course, an almost (but not quite) immediate increase in permeability, which may be easily detected by subsequently placing the tissue in acid (see Table II); but acids, even in very dilute solution, lead (Osterhout, 1914) to a decrease of permeability, even toward themselves, which removes much of the objection to this procedure.

² It is perhaps necessary to state that the observed variations are not traceable to differences in the acid preparations. The temperature coefficients of acid diffusion will be considered in a subsequent paper.

³ In this connection see Loeb and Cattell (1915) and Loeb (1915).

TABLE II.

The effect of preliminary treatment with distilled water upon the penetration time of acids. Typical data from one set of tests. Temperature = 24°C. The "control" gives the penetration time observed with similar tissue immersed directly in acid. There are added for comparison measurements with corresponding pieces of tissue killed by 1.0 per cent formaldehyde.

Animal.	In distilled H ₂ O.	Acid.	Time of penetration.	Control.	Dead tissue
	min		min.	min.	min.

Table III contains a summary of the data on caproic, fumaric, and maleic acids, which are shown graphically in Fig. 1.

TABLE III.

The Penetration Time, Min., of Caproic, Maleic, and Fumaric Acids.

Acid	Penetration time, 27 °C												
Dilution	10	5	17	5	20	25	50	100	150	200	300	400	500
Caproic						2 3		4 7		9 3	17 0	25	61
Maleic	3 6				4 4		8 1	19 4		28 0		55	
Fumaric			4 6	5 4			13 0	27 6	40 0	55 0	80 0		

FIG. 1. Penetration of *Chromodoris* tissue. 27.0°.

II. The lipid solubility of the monobasic fatty acids, aside from formic, follows the order shown in Table IV (quoted from Harvey, 1914, p. 468). This is precisely the order in which these acids, with the exception of caproic, had previously been found to affect the intracellular indicator of the *Chromodoris* tissues (Crozier, 1916). Caproic is now added to the list, and it will be noted that this acid also fits into the series (see Fig. 1).

TABLE IV.
Relative Lipoid Solubilities, Quoted from Harvey (1914).

Acid.	Caproic.	Valeric.	Butyric.	Propionic.	Acetic.
Partition coefficient. Xylol / water	3.5	0.6	0.1	0.02	0.00
Olive oil / water	7.25	1.78	0.44	0.14	0.05

The fact that in their first parts the curves for valeric and caproic acids are so near together, and even cross each other, does not interfere with this interpretation, since both are so far removed from the other weak fatty acids. The intracellular color change is an end result which involves several preliminary processes; one of these consists in the alteration of the cell surface to such an extent that the acid may enter; another consists in the diffusion of acid through the protoplasm. Provided the lipoid solubility of an acid be sufficiently great to speedily accomplish the former effect, it is not probable that an increase in lipoid solubility beyond this point would be markedly more efficient.

The view that this parallelism really indicates the method whereby these acids gain access to the interior of the integumentary cells of *Chromodoris* may be open to several qualifying objections, having reference to the variation of the partition coefficient with acid concentration, the nature of the lipoids possibly situated at the cell surface, and other similar points. There is, however, a correspondence between the penetration and solubility series, which is to a certain extent quantitative and cannot be ignored. Caproic and valeric acids are many times as soluble in olive oil or xylol as are the rest of the fatty acids, and they are similarly set apart from butyric, propionic, and acetic in the order of their cell penetrating ability. This is also true, in the same sense, for the concentrations of these acids necessary to reverse the phototropism of copepods (Loeb, 1911, p. 476). The combination of these acids with fatty substances situated at the cell surface enables the weak fatty acids to penetrate the cell in a sequence which has no reference to acid strength, either among themselves or in relation to other acids (compare Crozier, 1916).

III. Maleic and fumaric acids are of particular interest, because they may be closely compared with reference to the rôle

of ionization in determining cell penetrating power. Harvey (1914) found that from 0.01 N solutions fumaric acid required 12 to 15 minutes, maleic acid 20 minutes, to penetrate the testis epithelium of *Stichopus ananus*. With this sequence my values (27.6 and 19.4 minutes, respectively) do not agree.

The near position of the curves for succinic, maleic, and fumaric acids, having respectively the ionization constants 0.00665, 1.17, and 0.093, is sufficient in itself to show that ionization is not the sole determinant of penetrating ability. Yet the order maleic > fumaric, succinic bears out the conclusion previously arrived at (Crozier, 1916) that, when closely related acids are considered, their sequence in affecting the intracellular indicator is controlled by acid strength, provided the ionization is neither too high nor too low.

SUMMARY.

IV. The penetrating ability of caproic, maleic, and fumaric acids has been tested for the indicator-containing tissue of the nudibranch *Chromodoris zebra*. The positions of these acids with relation to the eighteen previously studied are such as to support the conclusion derived from the latter; namely, that for any given acid at least two factors determine its relative position in the penetration series. One of these influences is ionization, the second concerns more particularly the union of the acid with one of the several constituents of the cell surface. In the case of the weak monobasic fatty acids, this constituent is of a fatty nature.

FEEDING EXPERIMENTS ON THE SUBSTITUTION OF PROTEIN BY DEFINITE MIXTURES OF ISOLATED AMINO-ACIDS.¹

BY H. H. MITCHELL.

(From the Department of Animal Husbandry, University of Illinois, Urbana.)

(Received for publication, June 19, 1916.)

Investigations concerned with the question of the indispensability of amino-acids to the animal organism and with their precise significance in metabolism, have been pursued notably along two general lines. The first line of investigation, although followed by several workers independently with varying results, has been perfected by Abderhalden and has given the most fruitful results in his hands. The method is based upon the fact, which has been repeatedly proven experimentally, that the animal organism can be maintained in equilibrium and can even exhibit considerable increases in weight and nitrogen when the nitrogenous requirements are covered by preparations obtained by hydrolyzing protein material with enzymes until no positive biuret test can be secured, when presumably only amino-acids and probably the simpler polypeptides were present. One of the most successful experiments of this nature was recently reported by Abderhalden.² In this experiment a dog was kept for 100 days on a hydrolyzed meat preparation (ereptone) supplemented by non-nitrogenous nutrients. During this time the animal behaved normally, seemed in perfect health, and increased in weight from 13.75 to 23.10 kg. Similar successful experiments in which completely

¹ The results presented in this paper formed part of a thesis submitted by the author to the Graduate School of the University of Illinois in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry.

² Abderhalden, E., *Z. physiol. Chem.*, 1913, lxxxiii, 444.

hydrolyzed preparations³ were used during some of the periods have been still more recently reported by the same investigator,⁴ using dogs and rats as experimental subjects.

On the basis of such results the essence of Abderhalden's method was to remove certain amino-acids from the unknown mixture of the products of protein hydrolysis as completely as available methods would permit, and to determine the nutritive value of the residual mixture of amino-acids by testing its ability to maintain body weight and nitrogen equilibrium when fed to experimental animals in an otherwise adequate ration as the sole source of nitrogen. If the residual mixture proved itself of equal nutritive value to the original, the conclusion seemed justified that the amino-acid or amino-acids removed were not indispensable to the body, but could be synthesized from other compounds, provided, of course, the removal was reasonably complete. If the residual mixture of amino-acids was clearly inadequate to cover the nitrogen requirements, the proof of the indispensability of the amino-acid or amino-acids removed was completed by adding again to the ration the substances removed (isolated in a pure condition) and thus restoring its complete nutritive value. In cases in which the mixture was still inadequate after such addition, no conclusions would be justified. Such ambiguous results might be produced, for example, by the removal of substances other than those intentionally removed, by the incomplete removal of reagents, such as mercury salts, which may exert a harmful effect on the animal organism, or by chemical changes in the residual amino-acids incidental to the removal of those under investigation.

In Abderhalden's laboratory this method has been applied with striking success in many instances. The inability of the body to synthesize tryptophane and tyrosine has been repeatedly and clearly shown. In these experiments the tryptophane was removed according to the method of Hopkins and Cole with mercuric sulfate in 5 per cent sulfuric acid solution, and the tyrosine

³ The completeness of hydrolysis in these cases was determined by amino nitrogen determinations before and after boiling with concentrated mineral acid. These preparations were submitted first to the prolonged action of gastric, pancreatic, and intestinal juices or extracts and were then digested for 8 to 10 hours on the water bath with dilute sulfuric acid.

⁴ Abderhalden, *Z. physiol. Chem.*, 1915, xcvi, 1.

by concentration of the neutralized solution *in vacuo*. The addition of tryptophane or tyrosine, respectively, to the residual mixtures in most experiments had a distinct effect in correcting their nutritive deficiencies entirely, as indicated by the maintenance of body weight of the experimental animals to which the mixtures were fed, and the restoration of a positive balance of nitrogen. Furthermore, in his more recent experiments Abderhalden has shown that tyrosine cannot be substituted by the corresponding keto acid, oxyphenyl pyruvic acid, or by phenyl pyruvic acid, nor could it be substituted satisfactorily in most experiments by phenylalanine, in accordance with the work of Embden and Baldes.⁵ Some improvement, however, in nitrogen equilibrium was noted upon the addition of phenylalanine to the tyrosine-free ration, suggesting possibly a partial oxidation of this amino-acid to tyrosine.

The work on the nutritive value of tryptophane and tyrosine reviewed above embodies the only entirely successful results obtained with the method. Attempts to determine the nutritive value of proline and cystine have not led to results sufficiently clear cut to warrant final conclusions, while still less encouraging are the experiments to test the diamino-acids, by removal according to the procedure of Kossel and Kutscher.

Henriques and Hansen⁶ have published the results of an experiment similar in character to the work of Abderhalden, which led them to conclude that the diamino-acids could be entirely dispensed with by the animal body. The experiment was performed on a rat and the ration contained, besides non-nitrogenous constituents, a mixture of the products of protein hydrolysis containing presumably only monoamino-acids. It was prepared from an enzyme digest of a protein by precipitation with phosphotungstic acid, filtration, removal of excess reagent from the filtrate, and evaporation to dryness *in vacuo*. Unfortunately the particular protein used was not mentioned, and the lack of all details of the phosphotungstic acid precipitation precludes any attempt to judge of the completeness of separation of monoamino- from diamino-acids. The experiment lasted only 26 days. During the last 17 days only were positive nitrogen balances obtained and they

⁵ Embden, G., and Baldes, K., *Biochem. Z.*, 1913, lv, 301.

⁶ Henriques, V., and Hansen, C., *Z. physiol. Chem.*, 1904-05, xliii, 417.

were such that they could hardly be said to constitute convincing evidence of the nutritive adequacy of the ration fed, especially in view of the fact⁷ that the determination of the total urinary nitrogen per day of rats, with the exercise of the utmost care as to collection and preservation, is subject to errors of 10 per cent or more, due to incomplete collection. The body weight increased slightly during the last half of the experiment, but during the last 3 days it declined slightly but consistently. It is unfortunate that the experiment was not continued further to determine whether this final decrease was significant or not. This criticism is especially justified by the many experiments that may be quoted on the feeding of synthetic rations, in which entirely erroneous conclusions may be drawn if attention is confined to the first 20 or 30 days of observation.

The second general method of investigation of the nutritive significance of the amino-acids to the animal organism is associated more especially with the names of Osborne and Mendel and their associates, and has given by far the most valuable results in their hands. The method consists essentially in the feeding of isolated and carefully purified proteins, obtained from a wide variety of sources, incorporated in basal rations otherwise adequate for normal growth or maintenance and composed of artificial food materials, in most part of known composition and containing at most but minimal percentages of nitrogen or protein. By this method different proteins have been clearly shown to have different values in nutrition, in one respect or another, and these differences have been traced with great success to differences in amino-acid content. Thus, the significance of some of the amino-acids has been made evident, either by noting the peculiar effect attendant upon their absence in proteins or their occurrence in minute amounts, or by observing the effects produced upon supplementing proteins by their addition.

Of the results obtained by Osborne and Mendel with this second method of investigation the most general biological significance is attached to the demonstration that lysine is essential for growth. Gliadin, the alcohol-soluble protein of wheat, when fed

⁷ Osborne, T. B., and Mendel, L. B., *Carnegie Institution of Washington, Publication No. 156*, 1911, pt. i, 12.

to rats as the sole protein in a ration, is capable of maintaining an animal for long periods of time at constant weight, but is not able to induce normal growth. A slow growth would often result, while at other times only maintenance was secured. This characteristic stunting with gliadin resulted even when the calorie intake was sufficient for optimum growth, and has been successfully traced⁸ to the low content of this protein in lysine, since upon the addition of lysine to the ration, normal growth could be secured.

Zein, the alcohol-soluble protein of the corn kernel, has been shown by Osborne and Mendel (and others before them) to be unable to support either growth or maintenance. Upon analysis, this protein has been shown to lack the amino-acids glyco-coll, tryptophane, and lysine. The addition of tryptophane to the protein renders it adequate for long continued maintenance,⁹ the further addition of lysine renders it adequate for fairly normal growth,⁹ but for normal growth a further addition of arginine, which is present only in small amount in zein, appears to be necessary.¹⁰

Recently, in an investigation¹¹ to determine the effect of different percentages of various proteins in the ration on the growth of white rats, Osborne and Mendel have shown that rations containing percentages of casein inadequate for normal growth may be rendered adequate by the addition of the sulfur-containing amino-acid cystine to the ration. These results are intelligible in view of the comparatively low cystine content of casein.¹²

In properly appraising the two general lines of investigation of the nutritive value of amino-acids briefly described—on the one hand, that method associated mainly with the name of Abderhalden, and, on the other hand, that exemplified best by the work of Osborne and Mendel—it must be granted that they have contrib-

⁸ Osborne and Mendel, *J. Biol. Chem.*, 1914, xvii, 332.

⁹ Osborne and Mendel, *J. Biol. Chem.*, 1915, xx, 378.

¹¹ Osborne and Mendel, *J. Biol. Chem.*, 1915, xx, 351.

¹² Whether the favorable influence of cystine when added to rations containing 9 per cent or less of casein was due to its sulfur content entirely and could be duplicated by other available sulfur-bearing compounds is open to question. It is to be noted that the ration as a whole, as well as the casein, was poor in sulfur.

uted much valuable information. Our conceptions of protein metabolism and protein requirements must be profoundly modified as a result of this pioneer work. The work of Osborne and Mendel, in particular, is worthy of the highest commendation. By working with small experimental animals and using artificially prepared rations, consisting in large part of carefully purified substances of definite composition, they have succeeded in performing numerous experiments under carefully controlled conditions. The results have been clear cut and unequivocal in most instances. However, no criticism of these methods would be complete without due account being taken of their limitations.

The limitations of the Abderhalden method are obvious. It is only applicable to those amino-acids that can be readily and quantitatively isolated (or practically so) from protein hydrolysates, and isolated by means of reagents that can subsequently be entirely removed from the residual mixture. Furthermore it is essential to the success of the method that the residual amino-acids are not changed or destroyed during the manipulations involved in the removal of the amino-acid or acids to be tested, nor by the reagents employed for this purpose. In view of the difficulty, if not the impossibility, of conforming to the above conditions in the removal of the large majority of the amino-acids from mixtures obtained from the hydrolysis of proteins, this method is seriously restricted in its usefulness. It seems probable, in view of the methods available for the quantitative separation of amino-acids, that the Abderhalden procedure cannot be of any lasting value without at the same time becoming so cumbersome as to be of little practical utility.

The limitations of the Osborne and Mendel method are also obvious. Its success depends upon a knowledge of the amino-acid content of the different proteins investigated. The extremely unsatisfactory condition of this knowledge as regards the large majority of the proteins studied needs no comment. The most striking results have been afforded by a study of the nutritive value of proteins totally or largely deficient in one or more amino-acids. But such proteins are few in number, apparently, and their characteristic effects may involve some peculiar proportions among those amino-acids that do occur in them, proportions which cannot be intelligently modified in the absence of reliable data as

to their precise nature. A lack of such data, in the case of phaseolin for example,¹³ has blocked any attempt to determine the cause of its inadequacy for either maintenance or growth. A similar situation exists in connection with the poor nutritive value for growth of many of the proteins of the leguminous seeds, such as vignin.¹⁴

Any intelligent supplementing of proteins with isolated amino-acids is also impossible in the absence of at least fairly reliable information of their amino-acid content. Thus Osborne and Mendel state¹⁵ that they did not attempt to supplement lactalbumin with purified amino-acids to determine whether normal growth could be secured with less than 9 per cent of this protein in the ration, on account of inadequate information as to its amino-acid make-up.

However, even though a good knowledge of the amino-acid content of proteins were available, due to the evolution of accurate analytical methods, a study of the nutritive value of native proteins and of native proteins supplemented by amino-acids can hardly be expected to reveal the nutritive values of each individual amino-acid, nor to determine whether each amino-acid may or may not be synthesized by the animal organism. Much less could such a method of study be expected to yield complete information as to quantitative amino-acid requirements. The impossibility of such attainments by the use of the Osborne and Mendel method rests in the impossibility of controlling the amino-acid intake absolutely and of experimenting with any desired combination of amino-acids. For example, the suggestive theory of Osborne and Mendel¹⁶ to the effect that the only reason for the destruction of any protein at all in maintenance might be to liberate a small amount of one or two, or at most a relatively small number of amino-acids, to engage in some "hormone-like physiological duty upon which proper metabolism might depend," obviously could not be tested by their method of experimentation.

Thus while it would be hazardous to attempt to predict to what extent scientific ingenuity will overcome the obstacles inherently

limiting the applicability of this method to the problems of amino-acid synthesis in the animal organism and of amino-acid requirements, it may be confidently asserted that only a very incomplete solution can be expected from even the most extensive experimentation with it.

The most direct method of attacking these problems, and the only method with unlimited possibilities, is the feeding of definite mixtures of isolated amino-acids, to the complete exclusion of proteins and all of their intermediary degradation products. It is the main purpose of this investigation to test the feasibility of this method of experimentation.

Several attempts to cover the nitrogenous requirements of dogs by substituting the protein of a ration by a mixture of purified amino-acids have been made by Abderhalden.¹⁷ After many unsuccessful trials one experiment of 8 days' duration is reported in which the most encouraging results were obtained. The difficulties encountered in the previous trials were, first, inducing the animals to consume the rations containing amino-acids, and, second, avoiding the digestive disturbances which such rations were especially liable to produce, such as vomiting and diarrhea. In the 8 day experiment above mentioned a mixture of isolated amino-acids in their naturally occurring forms, containing all of the amino-acids commonly obtained in the hydrolysis of proteins with the exception of oxyproline, was fed. Each day's ration consisted of 25 gm. of amino-acids, 50 gm. of a glycerol-fatty acid mixture, 2 gm. of cholesterol, 50 gm. of glucose, and 5 gm. of bone ash, the amino-acids constituting about 9 per cent of the total ration. Though the ration possessed no decided taste, it was a matter of great difficulty to induce the animal to consume it. It was necessary to feed the dog often with small portions of the food. During the 8 days of feeding the body weight was constant. A negative nitrogen balance was obtained on the 4th, 5th, 6th, and 8th days, though the average balance of the period was positive. During the subsequent 7 day period, when 25 gm. of hydrolyzed beef (with a smaller percentage of nitrogen) were substituted for the amino-acid mixture in the above ration, the body weight increased slightly and a much more favorable nitrogen balance was secured.

Another dog was fed for 6 days with a ration containing 22.1 gm. of the same amino-acid mixture, 2 gm. of hydrolyzed nucleic acid, 25 gm. of fat, 20 gm. of sucrose, 20 gm. of glucose, and 5 gm. of bone ash. The weight of the dog was practically constant throughout the period, though negative nitrogen balances were obtained on the 3rd, 4th, and 5th days of feeding. The experiment was terminated by the refusal of the dog to consume any more of the ration. Substitution of the amino-acid mixture by hydrolyzed meat in the above ration was followed by more favorable results, as in the preceding experiment.

¹⁷ Abderhalden, *Z. physiol. Chem.*, 1912, lxxvii, 22.

Abderhalden concludes from these two feeding periods that no physiologically indispensable amino-acid was absent from the mixture fed. This conclusion, however, must be considerably discounted by reason of the shortness of the periods of amino-acid feeding, and by the unsatisfactory nitrogen balances obtained. The objections inherent in such short feeding periods as occur throughout Abderhalden's investigations need no comment in view of the frequent experience, especially of American investigators, with rations that appear to be adequate for long periods of time, but that ultimately lead to nutritive failure. Quoting a significant remark in one of the papers of Osborne and Mendel:¹⁸

"If we had been content to discontinue the experiments after a reasonable period, many of the declines [in body weight] evidently associated with imperfections in the dietary and readily checked by a change in feeding, would have escaped attention."

Osborne and Mendel¹⁹ have recently reported briefly an attempt to cover the maintenance nitrogenous requirements of rats by a mixture of tryptophane, cystine, histidine, tyrosine, phenylalanine, proline, and ammonium citrate or urea. In their own words:

"All such attempts failed, even when the supply of energy in the form of non-protein substances was liberal and the food contained all of the necessary inorganic salts and 'food accessories,' and in addition at least 0.5 per cent of protein, present in the 'protein-free' milk. On such diets the rats declined just as rapidly as when the amino-acid additions were not made."

It is evident from this review of the few experiments concerned with the feeding of mixtures of amino-acids to the exclusion of

¹⁸ Osborne and Mendel, *J. Biol. Chem.*, 1912-13, xiii, 245 and 246. Further evidence of the unreliability of short feeding experiments is afforded by the work of Dr. Ruth Wheeler. According to this investigator (*J. Exp. Zool.*, 1913, xv, 210):

"Animals have a surprising power of getting along for a time on a qualitatively inadequate diet. Mice kept upon a ration in which two-thirds of the protein was gelatin and the other third casein did not show a decline in body weight for 21 days, although the ultimate decline of every animal fed upon this food showed it to be insufficient; another group made material gains in weight for 17 days on a diet upon which all ultimately lost weight rapidly and died unless the food was changed."

¹⁹ Osborne and Mendel, *J. Biol. Chem.*, 1916, xxv, 2.

protein that no conclusive results have thus far been obtained; that is, that no definite mixture of isolated amino-acids has been shown to be capable of supporting life indefinitely. With the purpose of discovering some such mixture, the experimental work reported below was undertaken. The results secured to date have not been entirely successful, but several points of interest have been observed that seemed of sufficient importance to warrant publication.

EXPERIMENTAL INVESTIGATION.

The Selection of Experimental Animals.—The arguments in favor of the use of the smaller experimental animals in nutrition work have been well summarized by Osborne and Mendel:²⁰

“The preparation of suitable pure food supplies on a scale sufficient for long periods and in economically procurable amounts is thereby rendered possible. The necessary scientific measurements and analyses can be conducted on a scale impossible for larger animals, and the problem of care and attention is equally simplified. Experiments can be duplicated without great effort and individual peculiarities eliminated by force of numbers. Furthermore, the various stages of growth and maturity are completed in the smaller animals within relatively short periods of time, so that the permanent effects of any dietary become apparent within a range of days or months that is not outside of ordinary experimental possibilities of observation. As illustrations of some of these features it may be recalled that the ultimate effects of complete inanition are apparent in 4 or 5 days²¹ in rats or mice; in dogs the fatal outcome may be delayed for many weeks. The duration of life in the white rat is about 3 years; about 280 days suffice to complete the entire period of growth to maturity.”

²⁰ Osborne and Mendel, *Carnegie Institution of Washington, Publication No. 156*, 1911, pt i, 6.

²¹ In the course of one of our feeding experiments with white mice we attempted to feed an amino-acid ration to a female mouse weighing 23.6 gm. For the first 4 days the food was untouched; on the 5th day, 1.5 gm. of ration were eaten. For the next 2 days the food was untouched and it was withdrawn on the 7th day, from which time the animal received water only. The body weight rapidly declined, though aside from emaciation no other symptoms of malnutrition, such as roughened coat, infected eyes, etc., were apparent. On the 15th day of observation, i.e., 10 days after the 1.5 gm. portion of food was eaten, the animal died at a weight of 11.0 gm., having lost over 53 per cent of its initial weight. From this observation it would appear that the resistance of mice to inanition is much greater than is indicated in the quotation cited.

In the experimental project reported below the main limiting factor was the amounts of amino-acids that could be bought or prepared. It was, therefore, considered expedient to use mice or rats for the work, and of these two species of animals mice were considered more satisfactory, since they are only about one-tenth as heavy as rats of equal age and consequently they require a much smaller amount of food for maintenance and growth. Their span of life is also shorter than that of the rat. It has been stated that the average life of a white mouse is less than 2 years, that they are sexually mature at 2 months of age, and are fully grown at 150 days or even less. It would therefore appear that the effect of any inadequacy in a ration would be manifested in an even shorter period of time with mice than with rats.

It is certainly of some importance to consider the suitability of mice (or rats) as experimental subjects, not only from the standpoint of experimental convenience and expediency, but also from the standpoint of the biological significance of any experimental results obtained. It is of no economic importance or of no human interest simply to determine the qualitative or quantitative food requirements of such animals as rats or mice, if such requirements are not indicative, in a general way at least, of the food requirements of all mammalian organisms.

One is apt to have the impression, probably largely on account of the great discrepancy in size between rats and mice and animals of any economic or other importance to man (including man himself), that these smaller experimental animals are inherently unsuited for investigation purposes, because any results obtained with them must possess a very limited significance. In opposition to such an impression stands the work of Folin and Morris²² on the great similarity in the composition of the urine and also in purine metabolism between the rat and man. The extensive investigations of Donaldson²³ on the growth of the white rat have revealed close similarities to man, the similarity extending even to the growth of the brain and spinal cord. The close parallelism between the results that Hart and McCollum²⁴ have obtained

²² Folin, O., and Morris, J. L., *J. Biol. Chem.*, 1913, xiv, 509.

²³ Donaldson, H. H., Boas Memorial Volume, New York, 1906, 5-26; also *J. Comp. Neurol. and Psychol.*, 1908, xviii, 345.

²⁴ Hart, E. B., and McCollum, E. V., *J. Biol. Chem.*, 1914, xix, 373.

with pigs and with white rats in their study of the influence of restricted rations on growth also testifies to the general biological significance of experimental results secured with rats and presumably, also, of those secured with mice.

Such concrete illustrations of the close biological relations existing between the different species of mammals lend support to the general practice among physiologists and investigators in nutrition and related fields—a practice that is perhaps too generally accepted and too seldom submitted to critical scrutiny—to attach a general biological significance to experimental results obtained upon one particular species, or more truly upon a few representatives of one particular species of animals. The main justification of this practice is that, though no extensive systematic investigations on the comparative physiology and metabolism of the different species of mammals have been attempted, the experimental findings upon a large variety of animals are all remarkably consistent with one another, if not actually confirmatory of one another. Those differences that have been found in the metabolism of different species of mammals are largely quantitative and not qualitative. Therefore it has been concluded that experimental results obtained with one species of mammals may be considered as at least qualitatively applicable to mammals in general. Obviously accurate observations on rats or mice should be considered as valuable, in their general applicability, as observations on any other species of animal.

Experimental Details.—The mice were confined in galvanized iron cages, 8 inches in diameter and 6 inches high. In most of the experiments two mice were confined in a single cage. A small amount of paper excelsior²⁵ was always kept in the cages.

The rations were placed in small porcelain crucibles, $1\frac{3}{4}$ inches in diameter at the top and about $1\frac{1}{8}$ inches in height, which were wired to the sides of the cages. To prevent undue scattering of the food, the top of the crucible was fitted with a flanged ring of tinned copper, the hole in the ring being about 1 inch in diameter. This was crossed by two wires, also of tinned copper, at right angles to each other, so that there were four holes through which the mice could insert only their heads. With this device it was

²⁵ The paper excelsior used in all of the work analyzed 0.80 per cent ash and 0.05 to 0.06 per cent nitrogen.

hoped that all scattering of the rations would be avoided, but almost invariably with the amino-acid rations considerable scattering would occur in spite of all precautions. In such cases, to insure a fairly accurate determination of the food intake, the cage was placed over a crystallizing dish of such size as to fit under it tightly. This prevented the inroads of any wild mice. To insure a good separation of food waste and urine, a piece of heavy filter paper about 4 inches square was placed immediately under the food crucible in the crystallizing dish. With these arrangements it was rare that a good determination of the food intake could not be made, though only at the expense of much time and patience. The food was weighed out once a day, at which time the uneaten food from the preceding day was determined. The mice were weighed once a day in the amino-acid experiments, and once every other day in the experiments with other rations.

Water was supplied to the mice from an inverted bottle (attached to the removable top of the cage) provided with a bent delivery tube protruding a few inches into the cage. This method is very satisfactory, if care is taken to insure that the delivery tubes are always full of water. This depends primarily on the bore of the tube, the angle at which it is bent, and the size of the opening at the end of the tube, which is necessarily constricted somewhat to prevent undue loss of water. Distilled water only was used.

The mice were kept in light and dry quarters. During the autumn months when no artificial heat was available, the temperature occasionally fell to 65° or even 60° F., but later after the installation of a radiator, the temperature always remained above 70° and was generally maintained between 75° and 80°. In the hottest days of summer the temperature often rose above 90° F., but at such times conditions were alleviated somewhat by the use of an electric fan.

The cages were cleaned out once a day generally, and in all cases at least once every other day. They were sterilized whenever such measures were required (generally once in 1 or 2 weeks) by passage through a hot solution of strong alkali and thorough rinsing with water.

The amino-acids used in the feeding experiments were mostly prepared from protein material. The tyrosine, cystine, glutamic

acid, lysine, histidine, and arginine were prepared in the usual way from various proteins after complete acid hydrolysis. The tryptophane was prepared from pancreatine digests of casein by the method of Hopkins and Cole. The valine was synthesized, and the aspartic acid, asparagine, leucine, alanine, glycocoll, isoleucine, and phenylalanine were bought on the market and were in most cases Kahlbaum products. The *l*-proline used in some of the rations was an impure product obtained by alcohol extraction of protein hydrolysates with acid and subsequent isolation of the copper salt. Oxypoline and serine were not available for any of this work.

Most of the amino-acids prepared in the laboratory were not of tested purity. The tyrosine and cystine used were found to contain very close to the theoretical percentage of nitrogen and one tryptophane preparation was likewise found to be a very good product as judged by this criterion.

Basal Rations for Maintenance.—In view of the fact that growth probably sets a higher standard as regards amino-acid requirements than does simple maintenance, the logical point of attack in this investigation appeared to be the amino-acid requirements for maintenance rather than for growth. Another argument in favor of this procedure was that adult mice, which would be used in maintenance experiments, could probably withstand the digestive disturbances anticipated in the feeding of amino-acid rations better than immature animals.

It was therefore necessary to decide upon a suitable basal ration for maintenance made up of food substances containing minimal amounts of nitrogen. The rations used by McCollum and Davis, consisting of dextrin, lactose, purified butter fat, agar-agar, and a synthetic salt mixture, besides protein, for which mixtures of amino-acids could be substituted in our experiments, seemed ideal for the purpose. Unfortunately we could not secure long continued maintenance of mice with such a ration, even when casein was used to cover the nitrogen requirements, the trouble seeming to rest with the salt mixture. The ration of Osborne and Mendel, consisting of protein 18 per cent, "protein-free milk" 28 per cent, starch 26 per cent, lard 10 per cent, and purified butter fat 18 per cent, was found to be capable of maintaining

mice for long periods of time, thus confirming the results of Wheeler.^{18, 26}

The main objection to such a ration in an experiment of this nature is the fact that the "protein-free milk" as prepared according to the directions of Osborne and Mendel always contains protein nitrogen. In attempting to obviate this difficulty we have slightly modified the method of preparing this product.²⁷ After precipitating the casein from milk by a slight excess of HCl, filtering off the coagulum, boiling for $\frac{1}{2}$ minute to coagulate the lactalbumin, and filtering off this precipitate, the solution was carefully neutralized to litmus with NaOH and again filtered, the filtrate being then evaporated to a thick paste on the water bath at 70°C. and dried in a current of warm air. The last filtration, which constitutes the modification introduced, removes about 0.1 per cent of nitrogen, presumably protein nitrogen, figured on the basis of the dried product, or one-seventh of the total nitrogen of the first filtrate. Some of the mineral salts are also removed, though the nutritive value of the preparation for maintenance does not seem to be impaired at all if it constitutes as much as 28 per cent of the ration. This modified preparation of "protein-free milk" was used in many of the feeding experiments reported below.

Feeding Experiments with Mixtures of Amino-Acids.—In the first attempts to cover the nitrogenous requirements of mice by defi-

²⁶ While the Osborne and Mendel casein and "protein-free milk" ration appears to be satisfactory for the maintenance of weight and health of white mice, it does not appear to be satisfactory for the production of offspring. Comparatively few cases of pregnancy were observed with mice on this ration. Where pregnancy occurred birth was generally premature, apparently, and the young were generally eaten by the mother within 24 or 48 hours. In the course of over a year's experience only three young (out of a litter of five) were successfully raised until weaning, on this ration, and in these cases growth during the nursing period was noticeably slower than normal.

²⁷ Mitchell, H. H., and Nelson, R. A., *J. Biol. Chem.*, 1915, xxiii, 459. It might be said that practically all of the investigation work reported in this paper was completed before the trichloroacetic acid method of preparing protein-free milk was elaborated. This method, while probably better suited to the purposes of this work than any other, was not used in the preparation of any of the rations tested.

nite mixtures of amino-acids, the Osborne-Mendel ration was modified simply by the substitution of the 18 per cent casein by 18 per cent of definite mixtures of amino-acids, containing fifteen or fewer of the seventeen amino-acids commonly found in proteins, the two amino-acids lacking being serine and oxyproline. The proportions of the individual amino-acids included in these mixtures were more or less arbitrarily chosen, since there is little information at hand that would logically furnish a presumption in favor of any one mixture as opposed to others. In preparing these (as well as other mixtures tested) some consideration was given to the available analyses of pure proteins known to be complete for maintenance and growth; more consideration was necessarily paid to the stock of amino-acids on hand.

The results of the feeding experiments with 18 per cent of amino-acids were not successful and will not be given in detail. In all cases a decline in weight began as soon as the amino-acid rations were given, and in all cases the food consumed per day was light, especially as the experiment continued, so that it cannot be said that the failure to maintain weight was due to an incomplete amino-acid intake any more than to an incomplete energy intake. In several cases the mice on these amino-acid rations died within 2 weeks, and in other cases after longer periods. Four of the mice that died showed symptoms of severe diarrhea. The other six mice that died on the amino-acid rations showed no outward symptoms of digestive disturbance. No postmortem examinations of these mice were made.

The most successful of these preliminary experiments were run on two male and two female mice. The former two mice weighed from 20 to 21 gm. at the beginning of the experiment and were kept on rations containing mixtures of the 15 amino-acids available, for 27 days. At this time they had lost 37 and 45 per cent of their original weight. The two female mice weighed from 18 to 18.5 gm. initially and were kept on an amino-acid ration for 28 days, at which time they had lost 37 and 43 per cent of their weight. The condition of these four mice at the end of 27 and 28 days was obviously poor. Their hair was rough, emaciation was extreme, and they were so weak that they could barely use their hind legs. Upon changing to a ration containing 18 per cent of casein, recovery of the original weight occurred slowly in three

cases. In one case recovery was not complete, though the health and condition of the animal was apparently restored.

At this stage of the investigation the publications of Osborne and Mendel¹¹ and of McCollum and Davis²⁸ on minimum protein requirements appeared, in which it was shown that the protein requirements for the maintenance of rats may be covered by rations containing as low as 3 or even 2 per cent of protein. A plan for further work with the amino-acid rations immediately suggested itself. By lowering the percentage of amino-acids in the ration it was hoped that the food intake of the mice could be raised to normal and thus assure a fair test of the amino-acid mixtures, provided that the diminished consumption of the 18 per cent amino-acid rations was due simply to some disagreeable flavor imparted to the rations by the amino-acids contained in them.

This plan was first tested with a ration containing 8.1 per cent of a mixture of six amino-acids:

	<i>per cent</i>
Tyrosine.....	1.0
Cystine.....	1.0
Glutamic acid.....	4.0
Tryptophane.....	0.6
Histidine.....	0.5
Arginine.....	1.0

This ration was given to a male mouse with an initial weight of 21.4 gm. For the first 9 days the food intake was adequate, apparently, in covering the energy requirements, being from 2 to 3 gm. per day. The body weight decreased steadily, however, probably due to an inadequate amino-acid intake. On the 9th day the mouse weighed only 15.6 gm. From the 9th through the 50th day of the experiment the amino-acid ration was alternated in an irregular fashion with a non-nitrogenous ration, containing neither protein nor amino-acids except in so far as these are contained in "protein-free milk."

The introduction of the non-nitrogenous ration exerted a decidedly favorable influence on the body weight, which showed no tendency to decrease during the next 16 days of observation—on the 25th day of observation the weight of the mouse was 15.2

¹¹ McCollum, E. V., and Davis, M., *J. Biol. Chem.*, 1915, xx, 415.

gm. However, from here on, a slow decline ensued. During the period of mixed feeding the food consumption was much better on the non-nitrogenous than on the amino-acid rations, and almost invariably a day's feeding of the former when immediately preceded by a day's feeding of the latter ration produced a more or less clearly marked increase in body weight. For 50 days this mouse was kept alive on rations containing no appreciable amount of protein. Towards the last of the test the animal was in very poor condition and weighed 11.4 gm. on the 50th day. An attempt at recuperation on rations containing small amounts of casein (2 to 3 per cent) supplemented with cystine and tryptophane failed, and the mouse died on the 58th day of the experiment at a weight of 10.2 gm. The total loss in weight amounted to about 52 per cent of the initial weight.

A somewhat similar experiment to that just described was undertaken with a male and female mouse each weighing initially about 23 gm. For the first 9 days of the experiment these mice were put upon a non-nitrogenous ration and they declined steadily and rapidly in weight. From the 9th to the 40th days non-nitrogenous and amino-acid rations were fed alternately, as in the preceding experiment. The decline in weight still continued, but at a distinctly more moderate rate, though the food consumption was not noticeably increased, decreasing slowly, in fact, both absolutely and per 100 gm. of body weight.

These two experiments showed that the body weight curves of mice on amino-acid rations could be favorably affected by interposing non-nitrogenous rations alternately with the test rations. This favorable effect may be due simply to the fact that the former rations were consumed in larger quantities than the latter so that the energy requirements could be covered, or at least more nearly covered, than on amino-acid rations entirely. While this régime at the same time lowers the intake of amino-acids, it might still be consistent with nitrogen equilibrium in view of the known low protein requirements for maintenance of rats, and presumably also of mice. Therefore a series of feeding experiments were planned to test the value of various amino-acid mixtures which were included in percentages ranging from 2.5 to 9 in rations containing 28 per cent of "protein-free milk" (in some cases the modified preparation described above), 26 per cent starch, 10 per cent

lard, 18 per cent butter fat, and sufficient sucrose to make the ration up to 100 per cent. These amino-acid rations were fed alternately with a non-nitrogenous ration consisting of 10 per cent sucrose, 34 per cent starch, 28 per cent "protein-free milk" (in most cases the modified preparation), 10 per cent lard, and 18 per cent butter fat. A few of the more successful of these experiments, the results of which are represented graphically in Charts I to V, will now be considered.

CHART I. The upper two curves represent the changes in body weight of Mice 33 ♂ and 33 ♀. The circled points on the lower curve, representing the daily food consumption of the mice, indicate the days on which amino-acid rations were consumed. On the other days practically non-nitrogenous rations were given. For the period up to and including the 59th day the amino-acid ration used contained: 0.20 per cent histidine, 0.25 per cent glycocoll, alanine, valine, isoleucine, phenylalanine, proline, and aspartic acid, 0.30 per cent tryptophane, 0.37 per cent cystine, 0.40 per cent arginine and lysine, 0.45 per cent asparagine, 0.50 per cent leucine and tyrosine, and 0.75 per cent glutamic acid—a total of 5.62 per cent of amino-acids. This ration contained the most complete amino-acid mixture used in all the experiments reported; *i.e.*, fifteen acids. Of the amino-acids commonly occurring in proteins only serine and oxyproline are not represented. From the 60th to the 76th days inclusive the amino-acid ration used contained: 0.25 per cent isoleucine, cystine, tryptophane, arginine, histidine, valine, aspartic acid, and phenylalanine, 0.50 per cent tyrosine and leucine, and 1.00 per cent glutamic acid—a total of eleven amino-acids, making up 4.00 per cent of the ration. From the 77th day to the end of the experiment the amino-acid ration used contained ten amino-acids: 0.25 per cent cystine, tryptophane, valine, histidine, and phenylalanine, 0.50 per cent tyrosine, leucine, arginine, and asparagine, and 0.75 per cent glutamic acid—a total of 4.00 per cent.

In Chart I are recorded the results of a feeding experiment on two mice that were fed alternately, as indicated by the curve at the bottom of the figure representing the daily food consumption, a non-nitrogenous ration and an amino-acid ration containing

5.62 per cent of a mixture of fifteen amino-acids—the most complete amino-acid mixture tested in this investigation. Of the amino-acids commonly reported as occurring in protéins, this mixture lacked only serine and oxyproline. This system of feeding was continued for 59 days, during which period Mouse 33 ♂ decreased very gradually in weight from 24.4 to 12.6 gm., a total loss of over 48 per cent of the original weight. In the same period Mouse 33 ♀ decreased in weight for about 35 days from 21.7 gm. to a level of 12 to 13 gm. This level was maintained until the amino-acid ration was changed on the 59th day of the experiment; that is, for a period of over 3 weeks the weight of this mouse was maintained, though it was evident from its appearance that it was not in a good nutritive condition. On the 59th day of the experiment the amino-acid ration was changed to one containing 4 per cent of a mixture of only eleven amino-acids; *i.e.*, lacking glycocoll, alanine, proline, and lysine, as well as serine and oxyproline. The effect of this change was well marked on Mouse 33 ♀, which declined in weight continuously until its death on the 80th day of the experiment, at a weight of 10.1 gm. The total loss in weight of this mouse amounted to 53 per cent of the initial weight. However, the change in ration had no perceptible effect on Mouse 33 ♂, which continued its decline in weight at a uniform rate until its death on the 85th day of the experiment. The final weight of this mouse was 10.5 gm. and the total loss in weight during the entire experiment, 57 per cent of the initial weight. On the 77th day of this experiment the amino-acid ration was changed to one containing only ten amino-acids, as indicated on the chart.

A second feeding experiment, illustrated by Chart II, was undertaken with the second amino-acid ration used in the preceding experiment; *i.e.*, the ration containing 4 per cent of a mixture of eleven amino-acids. On this ration, alternated with the non-nitrogenous ration, Mouse 32 ♂ decreased in weight almost continuously (aside from the fluctuations caused by the alternation of rations) from an initial weight of 21.5 gm. to 15.5 gm. on the 35th day. At this point the weight increased rapidly for 4 or 5 days and then decreased suddenly. The mouse was found dead in the cage on the 45th day of observation, and was partially eaten by Mouse 32 ♀. At the time of this sudden increase in weight

CHART II The data for Mice 32 ♂ and 32 ♀ are presented in the above curves in a manner similar to the data in Chart I. For the period up to and including the 83rd day the amino-acid ration used contained 0.25 per cent isoleucine, cystine, tryptophane, arginine, histidine, valine aspartic acid, and phenylalanine, 0.50 per cent leucine and tyrosine, and 1.00 per cent glutamic acid—a total of 4.00 per cent of eleven amino-acids. From the 83rd day to the end of the experiment the amino-acid ration given contained: 0.25 per cent cystine, tryptophane, valine, histidine, and phenylalanine, 0.50 per cent tyrosine, leucine, arginine, and asparagine, and 0.75 per cent glutamic acid—a total of 4.00 per cent of a mixture of ten amino-acids.

the mouse had a puffy unhealthy appearance, probably due to an accumulation of water in the tissues. During the 45 days of observation this mouse lost 39 per cent of its weight. Mouse 32 ♀ decreased in weight regularly, but at a slower and slower rate; from about the 60th to the 94th day the weight was practically constant as is indicated by the weights tabulated below:

Weight of Mouse 32 ♀.	
Day of test	gm
55	12.4
60	13.0
65	12.4
70	11.8
75	12.2
80	11.7
85	11.5
90	12.3
95	11.7

On the 83rd day of the experiment the amino-acid ration was changed to one containing 4 per cent of a mixture of ten acids, the lack of isoleucine constituting the main difference between this and the preceding ration. On the 98th day of the experiment the mouse died at a weight of 9.8 gm., the total loss of weight during the entire experiment amounting to 50.5 per cent of the

initial weight. The mouse was active and appeared to possess a normal appetite until the last 5 or 6 days, when it became noticeably weak, assumed a very anemic appearance, and contracted some infection in one eye.

A third mouse, No. 50 ♂, was put on the amino-acid ration used for the first 82 days of the experiment just described, fed, as usual, alternately with a non-nitrogenous ration. For 12 days immediately preceding this system of feeding, the mouse had been on an amino-acid ration containing only 2.5 per cent of a mixture of eight amino-acids. Throughout the period of feeding on both of these rations the weight of the mouse declined slowly but steadily. The rate of decline was not apparently affected by the change in feeding instituted on the 12th day of observation. On the 57th day of the experiment the mouse died at a weight of 12.5 gm., having lost 44 per cent of its original weight (22.5 gm.).

CHART III. The data for Mice 46 ♀ and 46 a ♀ are presented in the above curves in a similar manner to the data in Chart I. The amino-acid ration used throughout the experiment contained 0.25 per cent cystine, tryptophane, valine, histidine, and phenylalanine, 0.50 per cent tyrosine, leucine, arginine, and asparagine, and 0.75 per cent glutamic acid—a total of ten amino-acids, accounting for 4.00 per cent of the ration.

In Chart III are given the results of an experiment on two mice to test the nutritive value of a mixture of ten amino-acids, constituting 4 per cent of a ration that was fed alternately with a non-nitrogenous ration. The proportions in which each amino-acid entered into the former ration are as follows:

	per cent		per cent
Glutamic acid.....	0.75	Cystine.....	0.25
Tyrosine.....	0.50	Tryptophane.....	0.25
Leucine.....	0.50	Valine.....	0.25
Arginine.....	0.50	Histidine.....	0.25
Asparagine.....	0.50	Phenylalanine.....	0.25
		Total.....	4.00

With this system of feeding Mouse 46 a ♀ decreased in weight from 17.7 gm. to a level of 10 to 11 gm. in a matter of about 30 to 35 days. This level was maintained until the 51st day of the experiment when the mouse was found dead at a weight of 10.2 gm.; that is, for a period of about 3 weeks. Mouse 46 ♀ decreased from an initial weight of 17.7 gm. to a level of 10 to 11 gm. in about 40 days. This level was maintained with insignificant changes until about the 70th day of observation, at which time a rapid falling off in weight occurred until the death of the animal on the 74th day at a weight of 8.9 gm. The following weights of this mouse illustrate the condition of practical maintenance existing from the 40th to the 70th days:

Weight of Mouse 46 ♀.

Day of test.	gm.
40.....	11.0
45.....	11.0
50.....	10.6
55.....	9.7
60.....	10.0
65.....	10.0
70.....	10.2

In this experiment Mouse 46 a ♀ lost 42 per cent of its initial weight, and Mouse 46 ♀ lost almost exactly 50 per cent.

CHART IV. The data for Mouse 48 ♂ are presented in the above curves in a similar manner to the data in Chart I. The amino-acid ration used throughout this experiment contained 0.25 per cent cystine, valine, and histidine, 0.30 per cent tryptophane, 0.45 per cent arginine, 0.50 per cent leucine, asparagine, and phenylalanine, and 1.00 per cent glutamic acid—a total of 4.00 per cent of nine amino-acids. It is to be noted especially that the ration contains no tyrosine.

254 Feeding Experiments with Amino-Acids

In the experiments thus far considered, tryptophane, tyrosine, and cystine, the amino-acids known to be indispensable for the maintenance of life, have in all cases been incorporated in the amino-acid mixtures tested. In Chart IV are given the results of a feeding experiment with an amino-acid ration containing 0.25 per cent of cystine, valine, and histidine, 0.30 per cent of tryptophane, 0.45 per cent of arginine, 0.50 per cent of leucine, asparagine, and phenylalanine, and 1.00 per cent of glutamic acid—a total of 4.00 per cent of nine amino-acids, among which tyrosine was not included. On this ration, alternated with the non-nitrogenous ration, Mouse 48 ♂ decreased in weight slowly but continuously from 22.1 gm. to a level of 13.0 to 13.5 gm. in the course of 40 days. This level was maintained for a period of 15 to 20 days, as the following figures show:

Weight of Mouse 48 ♂.

Day of test.	gm.
41.....	13.0
45.....	13.2
50.....	13.1
55.....	13.5
60.....	12.6

From this time on, the weight decreased slowly until the death of the animal on the 72nd day. The final weight was 11.0 gm. and the total loss in weight amounted to 50 per cent of the initial weight.

CHART V. The data for Mice 44 ♂ and 44a ♂ are presented in the above curves in a similar manner to the data in Chart I. The amino-acid ration used throughout this experiment contained 0.25 per cent cystine, valine, and histidine, 0.30 per cent tryptophane, 0.45 per cent arginine, 0.75 per cent leucine and asparagine, and 1.00 per cent glutamic acid—a total of 4.00 per cent of amino-acids. It is to be noted that this ration contained only eight amino-acids and, in particular, is lacking in tyrosine and phenylalanine.

A still less complete amino-acid mixture than the above was tested in an experiment the results of which are given in Chart V. The amino-acid ration used in this experiment contained 0.25 per cent of cystine, valine, and histidine, 0.30 per cent of tryptophane, 0.45 per cent of arginine, 0.75 per cent of leucine and asparagine, and 1.00 per cent of glutamic acid—a total of 4.00 per cent of amino-acids. It is to be noted that this mixture contains only eight amino-acids, and, in particular, lacks both tyrosine and phenylalanine. On this ration, fed alternately with the non-nitrogenous ration, Mouse 44 a ♂ declined comparatively rapidly from an initial weight of 24.0 gm. to a weight of 11.5 gm. on the 42nd day of feeding. A slight increase in weight preceded the death of this mouse on the 49th day of the experiment at a final weight of 12.6 gm., the total loss in weight amounting to 47 per cent of the initial weight. The decline of Mouse 44 ♂ was much more gradual, though continuous, and death ensued on the 72nd day of observation after a loss of 39 per cent of its initial weight.

The length of time that mice could be kept alive on mixtures of only a few amino-acids not including tyrosine or even tyrosine and phenylalanine, seemed remarkable. The withdrawal of tryptophane, however, appeared to exert a distinctly more detrimental effect. Three mice were fed alternately a non-nitrogenous ration and an amino-acid ration containing 0.25 per cent of cystine, valine, histidine, and phenylalanine, 0.45 per cent of arginine, 0.50 per cent of tyrosine, leucine, and asparagine, and 1.05 per cent of glutamic acid—a total of 4.00 per cent of nine amino-acids, excluding tryptophane. All three mice decreased continuously in weight. One died on the 33rd day after a loss of 32 per cent of its initial weight (22.8 gm.); another died on the 39th day of feeding, having lost 48 per cent of its original weight (20.1 gm.); the third mouse died on the 44th day of observation, the total loss in weight amounting to 44 per cent of its initial weight (22.0 gm.).

In studying the series of experiments just described on the nutritive value of different mixtures of amino-acids, one is struck by the fact that, aside from the mixture from which tryptophane was excluded, no clearly marked differences in nutritive value (with possibly one exception, mentioned above) are revealed as judged by the rate of decline in body weight or by the compara-

tive longevity of the experimental animals. The different mixtures were often strikingly different in general make-up, containing from eight to fifteen amino-acids in varying proportions. This general similarity in body weight variations is the more surprising in view of experiments on the feeding of isolated proteins inadequate for maintenance due to deficiencies in amino-acid content. These studies show that the different proteins exhibit more or less characteristic effects on the body weight of rats and mice. For example, phaseolin leads to a slow decline in body weight, zein to a more rapid decline, and gelatin to a still more rapid decline. As regards the last two proteins, Wheeler has shown²⁹ in the case of albino mice that with zein one-third of the body weight was lost in 25 days, while with gelatin one-third was lost in 12 days. It is true that the absence of data of the food intake precludes an analysis of the exact significance of such results. Furthermore, Osborne and Mendel³⁰ have shown that rations containing 2 per cent of proteins qualitatively adequate for maintenance have rather distinct characteristic effects on the rate of decline of rats, those containing edestin, for example, more nearly maintaining rats than those containing gliadin or glycine. Thus, it is natural to expect that amino-acid mixtures characterized by qualitatively different types of deficiencies should exhibit distinct characteristic effects, and that such effects were not produced in the experiments reported here is of interest.

In speculating on the causes of the decreases in body weight obtained with all of the amino-acid rations, it must be conceded that probably in no case was enough of the amino-acid mixture consumed to really constitute a fair test of its adequacy. Although the favorable effects of feeding the amino-acid rations used in these experiments, not continuously, but alternately with non-nitrogenous rations, seem evident, it seems to be a fact that this alternation of the two types of ration, while in most cases it assured a sufficient calorie intake, operated against the attainment of a sufficient amino-acid intake, unless this is much smaller than has hitherto been supposed.

It was surprising how the experimental animals could differentiate between rations containing no added amino-acids, and

²⁹ Wheeler, *J. Exp. Zool.*, 1913, xv, 215.

³⁰ Osborne and Mendel, *J. Biol. Chem.*, 1915, xx, 377.

those containing even very small concentrations of amino-acids. Inspection of Charts I to V is sufficient to show that the non-nitrogenous rations were in general consumed to a much greater extent than the rations containing 6 or 4 per cent of amino-acids. Even in the case of rations containing 2.5 per cent of amino-acids the same marked difference in intake has been observed. It seems impossible that this distinction could have been made on the basis of a difference in taste.

In order to be in a position to appreciate fully the above experiments, feeding tests were made on seven mice using the non-nitrogenous ration only, containing 28 per cent of the modified "protein-free milk." In all of these tests the mice decreased steadily in weight until death, though the periods of survival were different, as Table I shows.

TABLE I.
*Records of Mice on Non-Nitrogenous Ration.**

Mouse.	Period of survival.	Initial weight.	Final weight.	Total loss in weight in per cent of initial weight.
	<i>days</i>	<i>gm.</i>	<i>gm.</i>	<i>per cent:</i>
48 ♀	63	19.9	11.1	44
43 ♂	38	26.1	11.3	57
43 ♀	13	20.0	11.8	41
80 ♂	44	27.6	14.2	49
80a ♂	30	24.4	15.9	35
81 ♂	40	24.9	11.9	52
81a ♂	36	22.6	12.0	47

* This ration consisted of sucrose 10 per cent, starch 34 per cent, modified protein-free milk 28 per cent, lard 10 per cent, and butter fat 18 per cent.

It is evident from the results reported in this table that the periods of survival of the mice on the non-nitrogenous ration were distinctly less than the periods of survival of the mice in the more successful feeding experiments with the amino-acid and non-nitrogenous rations fed alternately. Aside from the exceptional behavior of Mouse 48 ♀, the survival periods of the mice on the non-nitrogenous rations are rather strikingly similar to the survival periods of the mice on the amino-acid ration not containing tryptophane; *i.e.*, 33, 39, and 44 days.

258 Feeding Experiments with Amino-Acids

That the longer survival of mice receiving amino-acids in their food as compared with mice receiving no amino-acids was not due to a more liberal consumption of food is shown in Table II, in which the average daily consumption of food per 100 gm. of body weight for successive 10 day periods is given (1) for the amino-acid experiments graphically represented in Charts I to V, and (2) for the feeding experiments with the non-nitrogenous ration just described. In the former case, the averages include both the amino-acid and non-nitrogenous ration, which were of approximately equal energy value.

TABLE II.

The Average Daily Food Consumption per 100 Gm. of Body Weight for Successive 10 Day Periods in Feeding Experiments (1) with Amino-Acid Rations, (2) with the Non-Nitrogenous Ration Only, and (3) with an Asparagine Ration. Results Expressed in Gm

10 day period	Amino-acid experiments					Non-nitrogenous experiments				Asparagine experiments	
	33 ♂ and 33 ♀	32 ♂ and 32 ♀	46 ♀ and 46a ♀	48 ♂	44 ♂ and 44a ♂	48 ♀	43 ♂ and 43 ♀	80 ♂ and 80a ♂	81 ♂ and 81a ♂	82 ♂	84 ♀
1	6 5	9 9	9 5	11 5	6 1	10 6	9 7	14 6	16 9	9 2	8 3
2	7 9	11 0	8 8	12 2	6 9	11 6		15 6	15 8	8 5	9 1
3	8 1	8 3	8 0	12 2	7 3	8 1	9 3	13 5	14 2	8 9	5 4
4	8 1	7 0	7 1	13 5	5 6	9 5		11 1		7 6	4 7
5	6 9	9 0	7 6	13 5	5 0	7 3				9 0	
6	6 6	9 6	5 9	9 8	8 5	8 6					
7	5 2	8 0	5 7	10 5	7 2						
8	5 8	9 3									
9		8 9									
10		5 3*									

* Average for 8 days only.

In the last two columns of Table II are given the average daily food consumption for two mice on a ration containing 10 per cent asparagine, 10 per cent sucrose, 24 per cent starch, 28 per cent modified protein-free milk, 10 per cent lard, and 18 per cent butter fat. On this ration Mouse 84 ♀ lived for 44 days, losing 56 per cent of its original weight, while Mouse 82 ♂ lived for 57 days, with a total loss of 50 per cent of the initial weight.

It can hardly be said that the asparagine ration was more successful than the non-nitrogenous ration as regards the period

of survival. However, it seems fairly conclusive that the amino-acid experiments as a whole were much more successful in this regard than the experiments involving the feeding of the non-nitrogenous ration, and that this difference in nutritive efficiency cannot be explained by a more liberal consumption of food in the amino-acid experiments; in fact, the reverse was more truly the case. It seems, therefore, that many of the amino-acid mixtures fed were utilized by the mice in some way in preserving intact the normal functioning of the tissues, possibly, as has been suggested, by furnishing the necessary precursors for the elaboration of the active constituents of the internal secretions, even though such mixtures were not sufficiently complete to make possible the synthesis of protein. These results, therefore, confirm the belief, rapidly gaining ground, that some if not all of the amino-acids occurring in combination in the protein molecule have specific functions in the animal economy aside from the function of serving simply as structural units in the elaboration of the body proteins.

According to the generally accepted theories of protein metabolism, a protein inadequate for maintenance, such as zein or gelatin, that is, a protein totally deficient in one or more of the amino-acids that are necessary for the construction of body protein because it cannot be synthesized by the body, would be of no use in metabolism except as a source of energy. However, McCollum³¹ has shown that the pig

"can utilize the nitrogen of zein very efficiently for repair of the losses due to endogenous or tissue metabolism. The average utilization of zein nitrogen was about 80 per cent, for gelatin 50 to 60 per cent. No evidence was obtained of the formation of additional body tissue from zein, even when the latter was fed in great excess over the maintenance needs of the animals."

In other words, assuming a constant endogenous metabolism, these percentages of the nitrogen of zein and gelatin were retained by the animals and apparently utilized for some purpose other than the construction of protein tissue. Similarly, Henriques and Hansen³² have shown that the protamine clupein, consisting

³¹ McCollum, E. V., *Wisconsin Agric. Exp. Station, Research Bull.* 21, 1912.

³² Henriques and Hansen, *Z. physiol. Chem.*, 1906, xlix, 113.

of arginine to the extent of about 82 to 83 per cent, was inadequate for maintenance of the white rat, but that its nitrogen was, nevertheless, utilized to some extent in metabolism. Recently Abderhalden⁴ has reported experimental results tending to show that, if mice are subjected to protein starvation, while receiving plenty of the non-nitrogenous nutrients, and if in an immediately following period, alanine or glycocoll is added to the basal ration, these amino-acids effect a reduction of the nitrogen loss of the first period, indicating a specific utilization of these nitrogenous nutrients, even when fed singly.

Similarly, the results of the experiments of this paper show that mice survive longer on the feeding of *incomplete* mixtures of amino-acids added to a basal ration of non-nitrogenous nutrients, than on the feeding of the non-nitrogenous nutrients alone. The most successful experiments of the former type extended over periods 75 to 100 per cent longer than the more representative experiments of the latter type. It appears, therefore, that the requirements of the animal organism for amino-acids resemble its requirement for inorganic ions, in that for the maintenance of life over long periods of time a complete assortment both of amino-acids and mineral elements is essential, while at the same time each essential amino-acid and mineral element has a specific function in metabolism. Thus, incomplete mixtures of either amino-acids or mineral elements will partially cover the body's requirements in the proportion of their completeness, though the elaboration of new tissue, and probably the efficient repair of old tissue, will be impossible in the absence of only one of the essential constituents.

SUMMARY AND CONCLUSIONS.

1. Experiments are reported in this paper in which mice have been kept alive for 70 to 98 days by feeding alternately (1) rations containing 4 to 6 per cent of various mixtures of isolated amino-acids, 6 to 4 per cent sucrose, 34 per cent starch, 28 per cent protein-free milk (prepared either according to the procedure of Osborne and Mendel or to a modification of this procedure described in the text), 10 per cent lard, and 18 per cent butter

fat, and (2) a ration containing 10 per cent sucrose, with other constituents in the same proportion as in the first mentioned rations. In many of these experiments periods of 15 to 35 days' duration have been observed in which the mice practically maintained their weight.

2. The alternate feeding of an amino-acid ration and a non-nitrogenous ration (except for the nitrogen present in the protein-free milk) induced a better total consumption of food than feeding with an amino-acid ration alone, and in all other respects led to more successful results. However, it is probable that in no case was the amino-acid intake sufficiently large to assure a fair test of its adequacy.

3. Amino-acid rations containing no added tyrosine, or no added tyrosine and phenylalanine, did not give appreciably different results from rations containing these amino-acids. However, if tryptophane was absent from an amino-acid ration, the period of survival of mice fed this ration alternately with the non-nitrogenous ration was noticeably shorter than the periods of survival of mice kept on rations containing added tryptophane.

4. Mice could be kept for much longer periods of time on rations containing mixtures of amino-acids, including tryptophane, fed alternately with the non-nitrogenous basal ration, than when fed the basal ration alone. Furthermore, this difference in survival cannot be accounted for by a difference in energy intake. This fact has been interpreted as meaning that at least some of the amino-acids have specific functions in metabolism aside from that of serving simply as material for the synthesis of body protein. Other evidence from the literature is cited in support of this view, which is substantially the same as that recently and tentatively put forward by Osborne and Mendel.

In conclusion I wish to acknowledge the general supervision of this work by Professor H. S. Grindley, and the aid which his suggestions have contributed. The assistance of Mr. Anton Prasil and Mr. R. A. Nelson in the work of preparing and synthesizing the amino-acids used, is also appreciated.

THE DIGESTIBILITY AND UTILIZATION OF EGG PROTEINS.

BY W. G. BATEMAN.

(From the Sheffield Laboratory of Physiological Chemistry in Yale University, New Haven.)

(Received for publication, June 24, 1916.)

In 1898 Steinitz noted that the ingestion of raw egg-white by dogs was followed by vomiting and diarrhea. This interesting observation appears to have passed almost unnoticed, although no other native proteins are known to give rise to such digestive disorders. When these same facts were observed by Mendel and Lewis in 1913, their possible bearing on the wide spread use of raw eggs in various diets, especially by the sick, prompted the following study.

The Behavior of Egg-White in the Alimentary Tract.

Experiments with Dogs.

Native Egg-White.—Uncooked egg-white fed in any large quantity to dogs invariably caused diarrhea of more or less severity. The feces were soft, pasty, or liquid depending upon the amount of material ingested and upon the individual susceptibility of the subject. The more liquid stools were light in color, and of very offensive odor. Many of them contained much mucus, and residues of unchanged egg-white and of other foodstuffs. Upon standing the surface dried rapidly so as to assume a glazed or varnished appearance. Water extracts of the feces, when boiled, yielded varying amounts of coagulated protein material. The coagulation temperature varied from 68–73°. When an equal volume of saturated ammonium sulfate solution was added to the extract, the latter became turbid, but the grayish precipitate contained only a trace of protein. The addition of acid or of more saturated ammonium sulfate solution to the filtrate caused

the formation of heavy precipitates which acted like ovalbumin. The substance, however, could not be obtained in crystals. The protein in the feces, then, appeared to be unchanged egg-white. The stools of firmer consistency contained less coagulable material than those which were liquid or semi-liquid. Even the apparently formed stools sometimes yielded small amounts of protein upon extraction. In this connection Tsuchiya's (1909) statement that albumin is never found in real formed feces but is usually associated with diarrhea is pertinent.

After eating meals containing enough raw egg-white to induce diarrhea, the subjects usually lost weight to the extent of from 0.25 to 0.6 kilo, or from 3 to 8 per cent of the body weight. Some of the dogs remained stationary in weight, but none showed an increase in this respect.

Vomiting only rarely occurred in consequence of ingesting native egg-white and then only after the larger amounts. The ejected material was practically unchanged by its stay in the stomach.

In a few cases small intestinal hemorrhages were noticed, pointing to irritation of the intestinal mucosa. This occurred only after several days' feeding of the raw food or after much straining at stool.

These abnormal conditions ceased promptly upon substituting meat or "dog biscuit" for the egg-white and could be called forth again by the reverse. In no case was there any "hang-over" effect. Indeed the cessation of egg-white meals was usually followed by constipation. The digestive disturbances which result from feeding dogs native egg-white are, therefore, caused directly by this substance.

Urine, obtained by catheterization on those days when the animals had diarrhea, usually gave negative results when tested for albumin; but occasionally small amounts were found present. These samples of urine also contained very little indican, due no doubt to the rapid emptying of the gut.

Amount of Egg Necessary to Produce Diarrheal Symptoms.—The effects produced by the egg-white were roughly proportional to the amounts ingested. With dogs of 5.5 to 7 kilos in weight the white of one egg causes no or little effect, two eggs may cause softening of the feces, three cause marked softening, and four or

five induce more or less severe diarrhea. The last symptom, then, is brought about by the ingestion of 1 to 1.5 gm. of native egg-white per kilo of body weight. This figure is lower for the heavier animals since dogs weighing from 10 to 12 kilos may develop diarrhea by eating the whites of five to seven eggs. There is much variation in the sensitiveness of the subjects, however; for a large dog may be more easily affected than a small one by the same amount of protein.

Other Factors.—Diarrhea followed the ingestion of: (1) native egg-white unmixed with other foodstuffs; (2) native egg-white beaten with milk; (3) raw egg-white thoroughly mixed with cracker-meal and lard; (4) raw egg-white thoroughly mixed with cracker-meal and lard and well flavored with extract of beef. The first two types of meal produced the laxative effect more quickly than the other two, the stools being passed in 8 to 12 and 12 to 20 hours respectively. The presence of a secretagogue such as meat extract in fairly large amount had no effect on the time of appearance or on the severity of the diarrhea. When a meal containing the whites of four or five eggs was divided into three portions which were fed to the dog several hours apart, the abnormal stool was later in appearing than when the meal was eaten all at the same time, and the diarrhea usually not so extensive. Conversely, if three of four egg-whites were fed at each meal several liquid stools were passed each day.

Tolerance.—It was noticed that when the raw protein was fed for several days in succession its ill effects gradually waned. The time necessary for the abatement of the diarrheal action varied from 3 to 5 days. If then the ingestion were continued, there succeeded a period of alternate days of diarrhea and constipation after which time the egg ceased to exert any marked action. The tolerance thus developed lasted for a short time even after the feeding of the uncooked material was discontinued. These facts are brought out in the following typical protocol.

Dog 1, a healthy terrier bitch weighing 6.52 kilos, received every day a meal containing the whites of four raw eggs well mixed with 60 gm. of cracker-meal and 20 gm. of lard. On the 1st day this caused severe diarrhea with a fall in weight to 6.31 kilos. On the 2nd day the diarrhea continued and the animal vomited some of the meal—one of the rare cases when this happened. The weight fell to 5.96 kilos. The stool on the 3rd

day consisted of a smaller amount of semi-liquid feces. No further vomiting occurred but the weight fell to 6.9 kilos. On the 4th day the pasty feces were much smaller in bulk while the weight rose slightly. This improvement was followed on the 5th day by rather bad diarrhea but the weight was not changed and after this time there was no further loss in weight. The feces of the 6th day were small in amount and pasty. On the next 2 days no feces were passed. The 9th day's stool consisted of a large amount of fairly formed feces. On the 10th day no fecal matter was passed. The quantity of egg given was now increased to five whites but notwithstanding this the next 2 succeeding days showed well formed feces. On the 13th day the stool was small and somewhat pasty while it was well formed again on the next day. At this point the subject was put on a meat diet for 2 days. Then a meal containing the whites of five eggs failed to cause diarrhea. After 2 days more of meat diet, however, the whites of four eggs in the meal brought forth a liquid stool. In one subject this period of induced "immunity" lasted for 12 days.

This tolerance recalls that acquired by the dogs subjected to peritoneal injections of raw egg-white as observed by Cramer (1908). He found that the protein was partly used and partly excreted in the urine. The quantity utilized rose gradually after repeated injections. Hamburger (1902) and Oppenheimer (1904) have observed this as well. That all proteins do not appear in the urine after injection intraperitoneally was shown by Mendel and Rockwood (1905) who found that edestin and excelsin were not excreted by the kidneys after introduction in this way.

Utilization.—The finding of unchanged egg-white in the diarrheal feces showed this foodstuff to be poorly utilized. The extent to which it was used was roughly shown by extracting the 24 hour feces with cold water, boiling this extract, and drying the coagulated material. The feces were made easier to handle by adding bone-ash to the meals and the feces of one period were marked off from those of another with lamp-black. After the ingestion of four to five egg-whites containing 15 to 19 gm. of protein, from 30 to 50 per cent of this could be recovered as coagulum. The latter, of course, contained varying amounts of occluded substances. More exact estimates of utilization were furnished by determining the amount of nitrogen in the feces by the Kjeldahl method. This is open to the objection that a portion at least of the fecal nitrogen is not derived from the undigested foods but is contained in unadsorbed material of the intestinal secretion and in epithelial cells from the intestinal tract.

According to Hammerl, Kermanner, Moeller, and Prausnitz (1897) and Tsuboi (1897) a large part of the nitrogen in the feces comes from these sources. Still another portion may be derived from the organisms living in the alimentary canal, for Osborne and Mendel (1914) have shown that a not inconsiderable part of the feces may consist of bacterial residues. But while the method does not show the exact amount of material digested, the figures so obtained do serve to show the relative degree of utilization. The following protocols are typical.

Native egg-white, then, was poorly made use of by these dogs, since from 30 to 50 per cent of the amount ingested was wasted by being ejected with the feces. When Mendel and Lewis (1913) fed this material to dogs only about half of the nitrogen in the meals appeared in the urine for the following 24 hours as contrasted with almost all when meat, casein, edestin, and other proteins replaced the egg-white. Steinitz (1898) reported unchanged egg-white in the feces in considerable quantity but does not state the figures. Vogt (1906) and Falta (1906) found that the nitrogen in uncooked egg-white superimposed upon a standard diet was excreted much more slowly in the urine than that ingested in the form of other proteins. The former ascribes this to a slower rate of digestion and the latter to the longer time necessary to catabolize the larger cleavage products which he supposes adsorbed. Both explanations are fundamentally the same—the native egg-white resists digestive processes.

After the dogs had grown to tolerate the egg-white better, the utilization was better as well. For example, the feces passed by the subject described in the protocol under "tolerance" on the 9th and 12th days were analyzed for nitrogen with results shown in the following table.

TABLE V.
Improvement of Utilization with Tolerance.

		gm.	gm.	per cent
9	Raw egg-white.....	2.46	0.39	84.3
12	" " "	3.15	0.42	86.7

Dried Egg-White.—The material was prepared by drying native egg-white in the air at temperatures below 50°. 15 to 20 gm. of the dry powder dissolved in water and fed in the usual meal of cracker-dust and lard were as active in causing diarrhea as the raw egg-white itself. This was also true with the subjects of Mendel and Lewis who consider the dried egg-white dissolved in water as equivalent to the original material. Neither was the utilization of the egg-white improved by drying. Several samples were kept at a temperature of about 40° for periods varying from 3 to 7 days, but this again made little difference in their digestibility. Falta (1906) made experiments using desiccated material and found in three cases a utilization of 80 per cent, 80 per cent, and 61 per cent respectively, while the same dogs used almost 100 per cent of casein and gelatin. The method used by Falta was that of superimposition. The feces were usually not analyzed but one dog was noted as having diarrhea. LeClerc and Cook (1906), in the course of work on another topic, fed to a dog meals containing dried albumin, cracker-dust, and lard together with sodium phosphate. They give the following figures:

TABLE VI.

Nitrogen Balance on Diet Containing Egg-White (LeClerc and Cook).

Experiment.	Nitrogen.				Utilization.
	In food.	In urine.	In feces.	Balance.	
	gm.	gm.	gm.	gm.	per cent
1	16.72	9.55	9.90	-1.73	40.8
2	16.71	10.89	6.18	-0.37	63.0
3	17.52	6.62	13.85	-3.05	21.0

For the first and third experiments practically all the nitrogen was supplied in the form of egg-white, while for the second, half was in this form and half in egg-yolk. The differences in the balance and utilization are striking. On the last day it will be noted that the nitrogen in the feces was over twice that in the urine. These results may be compared with those given later in this paper.

To determine what effect standing might have on the dried egg-white, experiments were made with commercial albumin

which had been in the laboratory for some years. This caused diarrhea although not so severe as that induced by either the native or freshly dried protein. Its activity was not further diminished by being exposed to bright light for 2 months. The dogs showed considerable ability to overcome the effects of this substance. The following describes a typical case.

Dog 4 was a healthy terrier bitch weighing 6.3 kilos. Its daily meal consisted of 60 gm. of cracker-dust, 20 gm. of lard, and 15 gm. of commercial egg-albumin dissolved in 150 cc. of water. On the 1st day severe diarrhea developed and the utilization of the protein was only 76 per cent. Next day the diarrhea was much less extensive but the weight of the subject had fallen to 6 kilos. On the 3rd day no feces were passed but the quantity on the 4th day was large while the consistency was pasty. The utilization was now 82 per cent. On the 5th day there was only a small quantity of feces and this was true of the 7th day as well. On the alternate days—6th and 8th—the feces were large in quantity and on the last named day better formed. The utilization had risen to 86.5 per cent. The native egg-white and the commercial product act, then, in much the same manner.

In still other experiments the dried egg-white was fed without previous hydration or solution, only enough water being added to the meal to make it eatable. In these cases diarrhea did not generally occur. Water was left in the cages but no more was taken than usual. The quantity of urine was diminished and indican was usually present in notable amounts. The feces were delayed, sometimes not being passed until 23 to 25 hours after the meal. When finally passed they were soft, unformed, of strong odor, and contained much mucus. The utilization was better than in the previous experiments, since it was generally above 80 per cent. In a few cases, however, diarrhea did result from dried egg-white fed in this way.

Cooked Egg-White.—When dogs ate the well cooked whites of four to six eggs they did not display the ill effects attending the use of the same quantities of uncooked egg-white. Moreover, the cooked material was as effective in stopping the diarrhea caused by the raw eggs as was meat. The utilization was very good, being in the neighborhood of 90 per cent, as shown below. The marked difference in the metabolism of the same substance cooked on the one hand and raw on the other is brought out in the following tables.

TABLE VII
Nitrogen Balance of Dog 1.

Day	Meal	Nitrogen				Utilization
		In food	In urine	In feces	Balance	
		gm	gm	gm	gm	per cent
1	Cooked egg-white, cracker, lard	3 76	3 20	0 33	+0 23	91 2
2	"	3 76	2 91	0 39	+0 46	89 6
3	Raw egg-white, cracker, lard	3 81	3 10	1 87	-1 16	51 0
4	"	3 74	3 27	1 31	-0 84	62 2
5	Cooked egg-white, cracker, lard	3 76	3 15	0 43	-0 18	88 5

TABLE VIII
Nitrogen Balance of Dog 5.

Day	Meal	Nitrogen				Utilization
		In food	In urine	In feces	Balance	
		gm	gm	gm	gm	per cent
1	Cooked egg-white, cracker, lard	4 32	3 95	0 43	-0 06	90 0
2	Raw egg-white, cracker, lard	4 36	3 17	1 81	-0 72	58 5
3	Cooked egg-white	4 32	4 00	0 44	+0 12	89 8

It will be seen that the cooked egg-white was not so well utilized as meat. For this two factors other than the nature of the foodstuff may be responsible. One is, that the dogs were fed generously which led as usual to more waste; and the other is the presence in the meal of bone-ash, for Mendel and Fine (1912) have demonstrated that even small amounts of indigestible substances in the food cause a poorer use of protein. Kolpakcha (1888) found egg-white to be excellently utilized by dogs—95 per cent or better—even when large amounts were ingested. Although not specifically stated so, the material was probably cooked. Steinitz (1898), on the contrary, states that considerable quantities of coagulated egg-white were passed in the feces of dogs. The differences may possibly be due to variations in

the fineness of division since if dogs are allowed to bolt large pieces of hard-cooked egg-white, fragments of the same can generally be distinguished macroscopically in the feces.

The Temperature Necessary to Improve the Digestibility of Egg-White.—The above results show that simple heating of the native egg-white renders it more digestible and affords the organism a chance to make better use of it. At what temperature is this change effected? To determine this the egg-white was heated in a double-boiler for 30 to 45 minutes with constant stirring. At temperatures below 55° the substance suffered little impairment of its activity in causing diarrhea. This activity is, however, considerably decreased by heating at 55° or 60°. After being subjected to a temperature of 65° for half an hour the digestibility of the egg-white is still further enhanced while at 70° or above, the foodstuff becomes entirely innocuous. Above 55°, more or less coagulation takes place depending upon the degree of alkalinity of the egg-white, while at 70° the protein is entirely coagulated but is very soft and jelly-like in texture.

Experiments with Rats.

The subjects were large, healthy, white rats kept in sanitary cages and supplied plentifully with food and water. The meals consisted largely of separator-milk powder ("Klim") mixed well with varying amounts of egg-white, bread-meal, and lard.

When the diet contained 20 per cent of raw egg-white the feces of the subjects were not different from those of controls fed on a mixed diet although occasionally the presence of small amounts of coagulable protein could be demonstrated. When the proportion of egg-white was increased to 40 per cent half of the animals had softened feces, the scybala being larger and longer than normal. Such stools as these always contained unused protein. All the subjects up to this time gained in weight and maintained excellent condition. Tolerance for the unusual foodstuff was quickly gained since after 7 to 10 days' feeding the feces could not be distinguished in appearance from those of the controls.

Next, a new lot of animals were first fed a diet containing 60 per cent of raw egg-white. This caused diarrhea which in some cases was severe. In the latter contingency the body weight

decreased while the less susceptible animals, on the contrary, gained somewhat or remained stationary. The food was not relished so that the diminished intake played some part when weight was lost. The ill effects of the native egg-white were still more marked when the proportion in the food was increased to 70 per cent. Several subjects refused to eat after a few days, moping in the cages and neglecting to clean themselves. The feces now became quite liquid at times and often contained mucus. When the fecal matter dried it appeared as though varnished. In a final experiment the rats were fed a mixture of 80 per cent raw egg-white and 20 per cent milk powder of which they partook rather sparingly. They lost weight rapidly, all were afflicted with diarrhea, and after 10 days it was evident that their health was much impaired. Six of these animals while having diarrhea were killed with chloroform and the intestines examined. In half the cases everything was normal while the degree of intestinal inflammation perceived in the other three did not appear significant.

The use of cooked instead of raw egg-white was followed by no untoward effects. All the rats gained in weight and remained well and active even when the diet contained a large proportion of the coagulated protein.

Falta and Noeggerath (1905) fed rats a diet in which dry egg-white was the only protein. The animals did not live longer than 94 days in the most favorable cases. The weight steadily declined and death followed when the weight fell to two-thirds or three-fifths of its original value. The rats suffered from conjunctivitis and other eye diseases. Knapp (1908) reports similar results. All his rats experienced diarrhea and conjunctivitis. One soon died, the others following in from 17 to 24 weeks, after losing much weight. Maignon (1912) fed rats exclusively on egg-white, either raw or cooked, which was found entirely inadequate to sustain them. Weight was quickly lost in spite of the increased quantities of food ingested. Death occurred after various periods when the body weight had been much reduced—in some cases as much as 40 per cent. Frank and Schittenhelm (1912) also failed to nourish rats when the only protein furnished was egg-white.

Von Knieriem (1885) fed mice exclusively on dry egg-white. They could not maintain existence and some succumbed in 3 days. Röhmman (1914) used mice as subjects, feeding them mixed diets some of which contained egg-white. He concluded from the results of his experiments that this substance sustained life poorly in comparison with other proteins.

All the untoward effects noted by these investigators cannot be ascribed to the egg-white but more justly to the lack in the diet of important food accessories such as the vitamins. Osborne and Mendel (1911) kept rats growing well on rations containing cooked egg-white as sole protein for 170 days and the ensuing decline was arrested, not by changing the protein but by adding a small amount of butter fat. As regards the eye troubles, rats are prone to suffer from epidemics of conjunctivitis and other diseases if poorly nourished or kept in unsanitary surroundings. Both Falta and Noeggerath and Knapp experienced these troubles with other proteins in the diet than egg-white; but they appeared to be milder and more tractable in the former case.

Experiments with Rabbits.

The experimental animals were kept in metabolism cages and liberally supplied with mixed food. The raw egg-white was fed by means of a stomach sound.

1. Two rabbits each received the whites of two eggs. One passed a small amount of semi-liquid matter while the feces of the other and of a control which received an equivalent quantity of water were normal.

2. Two rabbits each were fed the whites of three eggs. One had moderate diarrhea while the feces of the other were pasty and increased in quantity above those passed on the mixed food.

3. Three rabbits each were given the whites of two eggs at 10 o'clock and the whites of two more at 2 o'clock. Two were afflicted with diarrhea of some severity. One of them ate most of the fecal matter in preference to food. The third animal passed a large amount of very pasty feces, the scybala being much larger than normal.

Von Knieriem (1885) fed three rabbits each a meal containing

	gm
Dry egg-white	15
Meat extract	5
Sugar	10
Horn shavings	2
Water, cc	225

The resulting feces were very soft and abnormal. Utilization of the egg-white in the three cases was calculated to be 61, 67.2, and 70.2 per cent respectively. The character of the feces and the poor utilization of the protein were doubtless due in part to

the presence in the food of the horn shavings which acted in the same manner as the indigestible substances used in the experiments of Mendel and Fine and Mendel and Lewis. Nevertheless, von Knieriem decided that egg-white was, in contrast to almost all other proteins, poorly digested. Mendel and Rose (1911) found it impossible to feed any large amount of native egg-white to rabbits without inducing diarrhea.

Experiments on Man.

Experiments were made with native egg-white and raw eggs upon a number of persons, and the cooperation of still others who were eating raw eggs in order to gain weight was secured. The data collected confirmed the points already brought out. Most of the subjects experienced diarrhea which generally abated after several days' ingestion of the raw foodstuff, and many complained of intestinal discomfort. The material was poorly utilized. These experiments will be discussed more in detail together with the question of the use of raw eggs in practical dietetics, in another place.

The results of these experiments are in accord with those of other investigators. Falta (1906) found raw egg-white to be utilized by man to the extent of 70 per cent. A still lower value, 50 per cent, was reported by Wolf (1912) who has described the peculiar behavior of this foodstuff when ingested by man. He did not observe diarrhea but the feces were of soft consistency. When raw egg-white was in the diet there was over twice as much nitrogen in the feces as when the food contained the same quantity of nitrogen in the form of other proteins. On one occasion the feces contained more nitrogen than did the urine. The latter did not contain albumin, a result in contrast to those of Hamburger (1902) and Cramer (1908) who claimed that albuminuria followed the ingestion of large doses of native egg-white by man. Previously Oertel (1883) had not been able to find albumin in the urine in such cases, and neither did uncooked egg-white cause an increase in excreted albumin in preexisting albuminuria. Wolf also noted that when either raw or cooked egg-white was superimposed upon a standard diet there was a delay in the excretion of nitrogen and sulfur, the delay being greater

in the sulfur elimination. He suggested that the sulfur complexes in the uncoagulated egg-white have considerable power to withstand the action of the digestive enzymes.

Explanations of the Behavior of Egg-White in the Alimentary Tract.

The Effect of Heating on Egg-White.

The improvement in the digestibility of raw egg-white effected by heating may be brought about by the increased temperature in four different ways. These are: (1) The temperature used in cooking kills any bacteria present; (2) heating changes the physical texture of the egg-white; (3) heating destroys enzymes normally found in this native protein mixture; (4) heating changes the chemical nature of the egg-white.

1. *Heating Kills Bacteria.*—That bacteria in the egg-white cause the diarrhea attending its use is improbable. It is true that Wiley (1908), Lamson (1909), Pennington (1910), Maurer (1911), and Stiles and Bates (1912) have reported a large percentage of the eggs examined by them infected. But the more recent work of Rettger (1913), who carried out far-reaching tests with the greatest care to prevent accidental contamination, led him to the opposite conclusion. Of the whites of 582 fresh eggs only seven, or 1.2 per cent, showed the presence of bacteria and some of these cases were unquestionably due to contamination. These results are supported by those of Horowitz (1902) and confirmed by Kossovicz (1913). And not only is egg-white usually sterile but it has strong antiseptic properties and in many cases a marked disinfectant action on bacteria as demonstrated by Laschtschenko (1909) and Rettger and Sperry (1912). The bactericidal properties are destroyed by heating the egg-white to 65-70°. In view of these facts it is unlikely that the unusual behavior of native egg-white in the alimentary tract can be due to bacteria.

2. *Heating Changes the Physical Texture.*—When raw egg-white is heated above 55° it coagulates and loses its properties as a viscid liquid. It is possible that this change is responsible for the bettered digestibility of the cooked protein especially since, as shown above, this improvement is not brought about by heating at temperatures too low to cause coagulation.

Two sets of dogs were fed meals exactly alike except that one

received native egg-white and the other cooked egg-white ground to a fine pulp. By the addition of water both types of meal were made as nearly of the same consistency as possible. Those meals containing the raw foodstuffs always caused diarrhea while the others did not.

For further evidence on this point there was added to raw egg-white enough sodium hydroxide to prevent coagulation when the mixture was heated even above 70°. By this treatment the egg-white was little altered, only becoming somewhat more viscid; yet when fed to dogs it failed to cause diarrhea.

Other experiments to be discussed later in detail also showed that the egg-protein could be made digestible without changing its fluid character.

While it may be said that the peculiar physical nature of the substance is not *per se* the factor giving rise to diarrhea and poor utilization, the protein does, nevertheless, act while in the stomach in an unusual manner. Beaumont (1833) was the first to discover that raw egg-white leaves the stomach more rapidly than other foods, including cooked egg-white itself. Some objections may be raised against these early observations because of the abnormality of Beaumont's subject; but that the protein does act in the manner described has been confirmed recently by Cannon (1905), and London and Sulima (1905). The former found the egg-white to pass through the pylorus at a rate comparable to that of the carbohydrates which are among the first foodstuffs to enter the intestine after ingestion whereas protein leaves the stomach slowly. The egg-white was the only protein to act in this way among those investigated. London and Sulima by means of intestinal fistulas found that the egg-white left the stomach in large gushes, often faster than the peristaltic waves. During its stay in the stomach it retained its alkaline reaction for some time or passed into the intestine in this condition. After feeding a dog native egg-white these workers recovered 73 per cent unchanged from a fistula in the ileum.

The amount of gastric proteolysis undergone by this protein, already decreased by its short stay in stomach, is still further diminished by another unusual property observed by Pawlow (1902); namely, that the egg-white acts ineffectively in stimulating a flow of gastric juice. It acts in this way only like

so much water. But even this is not the end of the story, for Abderhalden and Pettibone (1912), and Bizarro (1913) state that native egg-white offers considerable resistance to the action of pepsin. If the egg-white is heated, however, and especially if coagulated at 80°, it is more quickly acted upon by the pepsin than when uncooked, and hydrolysis proceeds farther. After the material is once coagulated the rate of digestion is lessened by heating at higher temperatures. The fineness of division of the coagulum also affects the rate of digestion.

We may picture this native protein, then, as quickly leaving the stomach, accompanied by scanty amounts of gastric juice and practically unaltered by pepsin. Perhaps this lack of gastric digestion is at the bottom of the egg-white's unusual behavior as a foodstuff. That it does have a bearing on the subject was shown by feeding dogs partially digested egg-white. The protein together with 0.2 per cent pepsin and 0.2 per cent hydrochloric acid was heated for several hours at 37°. The digestion was continued until the mixture upon neutralization gave a heavy precipitate, in the filtrates from which no coagulable protein could be detected. This material, which was little altered in texture from the original, was as inactive as cooked egg-white in causing diarrhea.

However, Cannon, and London and Sulima have shown that even coagulated egg-white leaves the stomach much more rapidly than other proteins, although less so than when in the native condition. When cooked it does, in contrast to the raw material, call forth an early secretion of hydrochloric acid with which it unites. But the difference in rate of gastric discharge is not enough to account for the differences in digestibility, so one must consider the behavior of the two in the intestine.

As stated above, the native egg-white in the stomach fails to cause a good flow of gastric juice. According to the mechanism which Bayliss and Starling (1902) propose for the action of secretin, it is probable that once in the intestine the raw egg-white meets comparatively little pancreatic juice since the amount of the latter is proportional to the quantity of acid entering the duodenum—a fact observed by Pawlow (1902) as well. Furthermore, Brūno and Klodnizki (1914) showed that no bile was passed into the intestine when raw egg-white was ingested.

Okada (1915) has confirmed this to the extent that in his experiments the secretion of bile was small and seemed to be dependent upon the degree of digestion undergone by the protein in the stomach. Coagulated egg-white always caused a good flow of bile.

3. *Heating Destroys Enzymes.*—In the intestine the digestion of the egg-white is still further checked by the pronounced resistance it exerts against the action of trypsin. Vernon (1904) found the antitryptic activity to be more marked with this protein than with any other. In solutions containing 0.5 to 1.0 per cent of raw egg-white the trypsin action on fibrin was lowered to only 2.7 per cent of the normal, while even one part of egg-white in 6,000 reduced the activity to 45 per cent of the normal. When the egg albumin was exposed to a temperature of 60° its antitryptic influence was not diminished and it retained a good deal of its inhibitory power even after coagulation at 100°.

The native egg-white, however, is unlike collagen which is not acted upon at all by trypsin; for Bayliss (1908) has shown that if sufficient time be allowed the enzyme will act as completely upon uncooked as upon cooked egg albumin. For some hours after being brought together the trypsin does not change the egg-white in the slightest degree and it requires over 70 hours before the digestion equals that of the cooked material under the same conditions. Hedin (1907), Cohnheim (1912), Abderhalden and Pettibone (1912), Long and Johnson (1913), and Bizarro (1913) have all demonstrated the strong antitryptic effect of egg-white which Hammarsten (1912) considers remarkable.

To explain this behavior the existence of a specific anti-enzyme, antitrypsin, has been postulated which is supposed to unite with the trypsin much as an antitoxin does with its corresponding toxin. A later view is that the trypsin is adsorbed by the colloidal egg-white which thus cuts down tryptic activity in much the same way as did charcoal in the experiments conducted by Hedin (1906, b). Recently Maxwell (1915) has shown that boiled starch adsorbs pepsin and so hinders its activity. That egg-white does act in this manner is suggested by the observations of Delezenne and Pozerski (1903), Vernon (1904), Gompel and Henri (1905), and Hedin (1907) who found that raw egg-white prevents the tryptic digestion of other easily digested proteins.

so much water. But even this is not the end of the story, for Abderhalden and Pettibone (1912), and Bizarro (1913) state that native egg-white offers considerable resistance to the action of pepsin. If the egg-white is heated, however, and especially if coagulated at 80°, it is more quickly acted upon by the pepsin than when uncooked, and hydrolysis proceeds farther. After the material is once coagulated the rate of digestion is lessened by heating at higher temperatures. The fineness of division of the coagulum also affects the rate of digestion.

We may picture this native protein, then, as quickly leaving the stomach, accompanied by scanty amounts of gastric juice and practically unaltered by pepsin. Perhaps this lack of gastric digestion is at the bottom of the egg-white's unusual behavior as a foodstuff. That it does have a bearing on the subject was shown by feeding dogs partially digested egg-white. The protein together with 0.2 per cent pepsin and 0.2 per cent hydrochloric acid was heated for several hours at 37°. The digestion was continued until the mixture upon neutralization gave a heavy precipitate, in the filtrates from which no coagulable protein could be detected. This material, which was little altered in texture from the original, was as inactive as cooked egg-white in causing diarrhea.

However, Cannon, and London and Sulima have shown that even coagulated egg-white leaves the stomach much more rapidly than other proteins, although less so than when in the native condition. When cooked it does, in contrast to the raw material, call forth an early secretion of hydrochloric acid with which it unites. But the difference in rate of gastric discharge is not enough to account for the differences in digestibility, so one must consider the behavior of the two in the intestine.

As stated above, the native egg-white in the stomach fails to cause a good flow of gastric juice. According to the mechanism which Bayliss and Starling (1902) propose for the action of secretin, it is probable that once in the intestine the raw egg-white meets comparatively little pancreatic juice since the amount of the latter is proportional to the quantity of acid entering the duodenum—a fact observed by Pawlow (1902) as well. Furthermore, Brūno and Klodnizki (1914) showed that no bile was passed into the intestine when raw egg-white was ingested.

When fed to dogs this material was effective in causing diarrhea. The antitrypsin, if present, is not diffusible. Cathcart (1904) found that the antitryptic action of blood serum is not removed by dialysis.

Egg-white was incubated with 0.2 per cent sodium or potassium hydroxide or 0.25 per cent sodium or potassium carbonate for several hours at 37°. Fed to dogs the material was no different in behavior than cooked egg-white. This treatment does not alter the texture to any extent.

The native protein was heated in an incubator at 37° for 4 to 8 hours with 0.2 per cent acetic or hydrochloric acid. By this treatment it was rendered digestible and no diarrhea followed its use. This process also left the original texture unaltered.

Jobling and Petersen (1915) succeeded in extracting antitrypsin from blood serum with chloroform. It was found impracticable to extract native egg-white with chloroform or ether since a considerable quantity of the protein was precipitated and the liquids, especially the chloroform, did not separate well. After standing for 12 to 24 hours the mixtures were dried rapidly in a current of warm air at room temperature. The dry material was thoroughly mixed with water and fed to dogs. It did not cause diarrhea. Nothing had been removed from the native egg-white and judging by the work of Jobling and Petersen the treatment was scarcely drastic enough to destroy the anti-enzyme.

Further attempts at extraction were made more successfully by previously drying and powdering the egg-white. In order to make the extraction as complete as possible the mixture of dry egg-white and ether or chloroform was allowed to stand for 4 days, on each of which it was well shaken for a period of 30 to 60 minutes. The extract was then separated and evaporated to dryness at room temperature. The residue from the extract was triturated with water and mixed as well as possible with finely minced, coagulated egg-white. This mixture, assumed to contain any antitrypsin originally in the egg-white, failed to cause diarrhea when fed to dogs. The residues insoluble in chloroform or ether were dried, mixed with water, and fed to dogs with negative results.

It is well known that enzymes in general are soluble in dilute and precipitated by strong alcohol. Egg-white was coagulated with strong alcohol and filtered. If antitrypsin was precipitated by

the reagent it should be contained in the coagulated protein; yet when this was freed from alcohol and fed to dogs it caused no diarrhea. Neither did the filtrate appear to contain antitrypsin, for the residue obtained from it by evaporation well mixed with cooked egg-white was fed to dogs with no untoward results. In still other experiments the egg-white was precipitated as before with strong alcohol. After filtering, the coagulated protein was finely minced, ground up with dilute alcohol, and finally washed with dilute alcohol. By this treatment it might be supposed that antitrypsin, if present in the egg-white, would first be precipitated and then washed out of the finely divided coagulum by the dilute alcohol. Accordingly the filtrates and washings were evaporated until the alcohol was removed and fed to dogs after being thoroughly incorporated with cooked egg-white. In no case was diarrhea induced. Finally the washed coagulum was fed but proved as ineffective as the extracts.

Those of the above experiments, therefore, which were planned to remove an active substance from egg-white—by extraction or washing—appeared to fail since the separated material did not render cooked egg-white indigestible. In contrast, those experiments calculated to make the native egg-white digestible by destroying the anti-enzyme were successful. It may justly be argued, however, that antitrypsin, even if contained in the residues from the extracts, cannot be mixed intimately enough with cooked egg-white to make it really indigestible.

4. Heating Changes the Chemical Nature.—When egg-white is coagulated its chemical nature is altered. This change may be the causal factor in bettering its behavior in the intestinal canal. Changes of like nature brought about by other agents than heat were similarly effective.

Some of the experiments already described bring out this point. Thus egg-white precipitated with alcohol did not affect dogs as did the original protein. It made no difference whether the precipitate was filtered off at once or allowed to stand in contact with the alcohol for several days. In other experiments the egg-white was denatured by the minimum quantity of moderately strong alcohol and the whole mixture dried quickly at a low temperature. This material sometimes considerably softened the feces of dogs by which it was ingested but this may be due to the fact that the treatment usually leaves some of the original protein unaltered.

It has already been stated that dried egg-white extracted with chloroform or ether was readily digested. When these residues, from which little had been removed by extraction, were mixed with water and fed to dogs they did not cause diarrhea. Sometimes, after the extraction had been made with ether, the feces were softer than normal. This lack of activity was not because the reagents extracted any active material as shown above, but apparently because the protein was more or less denatured by them. Before extraction the dried egg-white was entirely soluble in water, but the treatment so changed it that much of it became insoluble.

Egg-white was chemically modified in still another way by converting it into alkali-metaprotein. This was prepared by the gradual addition of potassium hydroxide to native egg-white with constant stirring. The transparent jelly was finely divided and thoroughly washed with cold water. Fed to dogs it proved an excellent foodstuff. The feces formed by it closely resembled the normal feces in being dry and crumbly. Klug (1897) found that pepsin from the stomach of dogs digested alkali-albumin better than any other protein in his list, at the bottom of which he placed coagulated egg-white. In general the same thing was true with pig and ox pepsin. Vernon (1904) considered alkali-albumin prepared from egg-white more easily digested by trypsin than the native protein.

As stated previously, if egg-white is partially predigested by pepsin or incubated with dilute acids and bases it loses its ability to cause diarrhea. All of these procedures, in addition to any effect they may have on antitrypsin, change the chemical nature of the egg-white. It is true that some of these changes are not pronounced, but in this respect the altered substances may be like the racemized proteins of Dakin and Dudley (1913) who found that such a slight chemical change as a partial reversal of the direction of polarization was sufficient to convert casein into an entirely indigestible substance.

Résumé.—From the evidence at hand it is reasonable to assume that the indigestibility of the egg-white is due primarily neither to its physical texture nor to any bacteria present. But it seems impossible to make a decision between the other two explanations offered, the difficulty being that any process affecting one

factor modifies the other as well. Thus, when incubation with acid improves the digestibility of the native protein, we may explain it from the one view-point as due to the destruction of the antitrypsin, and from the other as due to the conversion of the indigestible egg-white into digestible acid-metaprotein. When treatment with chloroform renders the egg-white digestible, we may assume that this is caused either by the removal or destruction of the anti-enzyme, or by the change effected in the chemical properties of the protein.

The simplest assumption is that raw egg-white is attacked with much difficulty by the digestive enzymes. It is not contended that raw starch, agar, collagen, cellulose, and other indigestible substances contain anti-enzymes. Moreover, the existence of such substances has been seriously doubted of late by investigators like Bayliss (1908) and Cohnheim (1912), the latter of whom considers that, "the evidence does not permit us to speak of specific antiferments." Probably the explanation of the behavior of antitryptic substances most in favor at present, is that which postulates an adsorption of the trypsin, the effective concentration of which is thereby reduced.

What Component of Egg-White Is Responsible for Its Peculiar Behavior in the Alimentary Tract.

The Action of the Individual Proteins of Egg-White.

The proteins of egg-white were separated from each other according to the method of Osborne and Campbell (1900). Care was taken to have the various fractions as free from each other as possible and each was dialyzed free from ammonium sulfate before being used. The amounts of the various proteins used were equivalent to those contained in the whites of five or six eggs, which amount of egg-white had previously been found sufficient to cause severe diarrhea in the dogs used as subjects.

Globulin.—According to Osborne and Campbell globulin is present in egg-white to the extent of 7 per cent of the total solids. The whites of five or six eggs contain approximately 1.5 to 2 gm. of globulin. These amounts of freshly prepared, moist globulin mixed with the usual meal did not affect the dogs in the least and the same was true when quantities four or five times as

large were ingested. Even 20 gm. of purified egg globulin prepared 2 years previously did not perceptibly alter the consistency of the feces, although it was not very well utilized.

Ovalbumin.—The ovalbumin was obtained in fine crystals. After being dialyzed it was quickly dried at a low temperature. Osborne and Campbell succeeded in crystallizing 50 per cent of the total proteins in egg-white but consider that all the other fractions contain more or less of this substance. While the actual proportion present is, then, somewhat doubtful, for these experiments it was assumed to be 60 per cent. The whites of five or six eggs would then contain 12.5 to 16 gm. of ovalbumin. Fed in these amounts to dogs it caused diarrhea which was more marked when larger amounts were ingested. Its action, however, was not so marked as might be expected from the activity of the native egg-white itself and was also more variable. Thus one dog, for instance, in which diarrhea had been induced several times with raw egg-white failed to react at all to the ovalbumin. Perhaps this is not surprising considering the amount of manipulation necessary to obtain the pure ovalbumin. While the globulin is separating the mixture becomes strongly alkaline from the formation of ammonium hydroxide, and another change—possibly oxidative—is going on as shown by the gradually deepening color of the solution. Later the ovalbumin stands for a long time in contact with acid, is dialyzed for several days, and dried. Osborne and Campbell indeed regard the crystallized substance as different from the original protein and consider that it is probably a combination of the protein with acid.

Conalbumin.—The amount of uncrystallizable albumin in egg-white is not definitely known but it is probably from 25 to 35 per cent of the total proteins. In five or six egg-whites there would be 4.5 to 6 gm. of conalbumin. Fed in these amounts it generally caused the formation of pasty feces, which effect was increased where the amount ingested was larger. A mixture of ovalbumin and conalbumin in the proportion in which they occur in egg-white fed to dogs in amounts equivalent to 85 per cent of the total proteins in five or six egg-whites caused diarrhea.

Ovomucoid.—It seems unlikely that ovomucoid is the disturbing protein of the egg-white since it is present in small amount—10 per cent according to Hammarsten,—is unaffected by heating

in boiling water, and is precipitated unchanged by alcohol, so that it was present in the alcohol precipitates which failed to cause diarrhea. This supposition was confirmed by feeding to dogs ovomucoid prepared as follows. The whites of five or six eggs were diluted with water and the globulin and albumins coagulated by boiling after the addition of a little acetic acid. The filtrate containing the ovomucoid was fed to dogs mixed with the usual meal but did not cause diarrhea.

The albumin fraction, therefore, appears to be the indigestible portion of the egg-white. This is in harmony with the observations of Mendel and Lewis who found that purified ovalbumin fed to dogs in comparatively large amounts caused profuse diarrhea. Vernon (1904) found crystallized albumin to be even more resistant to trypsin than native egg-white. Bainbridge (1911) noted that certain forms of bacteria do not appreciably break down this substance even in the presence of sufficient non-nitrogenous food to insure vigorous bacterial growth. In view of these results it is interesting that the antitryptic action of blood-serum according to Hedin (1904), Cathcart (1904), and Vernon (1908) is associated with the albumin and not with the globulin.

The Digestibility of Duck Egg-White.

Experiments with the white of the eggs of the Eastern Indian Runner demonstrated that it, too, was indigestible, caused diarrhea, and was poorly utilized. The egg-white of the common fowl, then, is not unique in its exceptional conduct as a foodstuff. The egg of the duck appears to have been little investigated but the white differs in appearance from that of the hen's egg, and Panormow (1906) thought that it contained a special protein not found in other eggs.

The Behavior of Egg-Yolk in the Alimentary Tract.

When egg-yolk was fed to dogs in any large quantity as part of a meal containing lard and cracker-dust, it usually caused a rather severe digestive disturbance of which vomiting was the main symptom. The vomitus contained much bile, and frequently comparatively large amounts of this liquid were expelled from the stomach. Diarrhea sometimes accompanied this

vomiting. The subjects were apathetic and had little appetite for several days. These effects were brought about by cooked as well as by raw egg-yolk. The picture of this digestive disorder is thus quite different from that induced by native egg-white.

The regurgitation of bile suggested the fat as the cause of the trouble. Therefore the lard was omitted from the meal with favorable results since no diarrhea or vomiting was then noted. The same end was attained by extracting the fat from the egg-yolk by means of ether. The crude yolk-protein, freed from ether, was fed with lard and cracker-meal to dogs, and was inactive. The dogs affected by egg-yolk in the way described seem, then, to have had a low tolerance for fat. The disturbing effect of the yolk is considerably less than that of the white; for while, in one case, the whites of four raw eggs caused diarrhea the same subject ate six raw yolks with impunity.

The egg-yolk and ovovitellin were found to be excellently utilized and there appears to be nothing in the literature to show that they are indigestible. Mendel and Lewis' (1913) experiments showed the excretion of nitrogen after feeding ovovitellin to be the same as that after meat, a result in opposition to that obtained with coagulated and uncoagulated egg-white where the nitrogen excretion was delayed. McCollum (1909) sustained life in white rats for 18 weeks on nothing but egg-yolk with no unfavorable results, while it may be recalled that Maignon, Knapp, and von Knieriem could not keep dogs, rats, or mice alive on egg-white alone. Laschtschenko (1909) found that bacteria thrived well on egg-yolk, that it does not possess germicidal properties, and cuts down the bactericidal action of the egg-white.

SUMMARY.

Raw egg-white is found to be a decidedly indigestible substance. It may cause diarrhea in dogs, rats, rabbits, and man when ingested in any large quantity. Its utilization by the body is poor since it is used only to the extent of 50 to 70 per cent. Subjects can acquire a certain tolerance for the native protein after ingesting it for several days so that it no longer causes diarrhea and is somewhat better utilized.

Raw egg-white can be made digestible through coagulation

by heat; by precipitation with alcohol, chloroform, or ether; by incubation with dilute acids or alkalis; by partial digestion by pepsin; by conversion into alkali-metaprotein.

The indigestibility of native egg-white probably lies either in its antitryptic content or in its chemical constitution. Its physical texture appears to play a minor part in its behavior.

Of the individual proteins constituting egg-white, the albumin fraction appears to be the indigestible component.

The whites of the hen's egg and duck's egg act alike in causing diarrhea and in being poorly utilized.

Egg-yolk either raw or cooked is excellently utilized. It sometimes causes digestive disturbances in dogs, apparently because of its high fat content.

A review of the literature shows that dietitians have relied, in general, upon the early observations of Beaumont as support for the use of raw eggs. These observations were in the main exact; but, so far as the digestibility of raw egg-white is concerned, were misinterpreted.

In current dieto-therapy raw whole eggs, raw egg-white, and albumin-water are extensively prescribed. There appears to be little in their conduct as foodstuffs, however, to warrant such faith in their nutritive value or ease of assimilation.

In conclusion it is a pleasure to thank Dr. Lafayette B. Mendel for his kindness and helpfulness during the course of this work.

THE EFFECT OF THE AMINO-ACID CONTENT OF THE DIET ON THE GROWTH OF CHICKENS.*

By THOMAS B. OSBORNE AND LAFAYETTE B. MENDEL.

WITH THE COOPERATION OF EDNA L. FERRY AND ALFRED J. WAKEMAN.

(From the Laboratory of the Connecticut Agricultural Experiment Station and the Sheffield Laboratory of Physiological Chemistry in Yale University, New Haven.)

(Received for publication, July 12, 1916.)

PLATE 1.

Experiments on the feeding of albino rats have shown that for adequate growth a suitable supply of certain amino-acids must be available in the diet.¹ Conspicuous among them are tryptophane, lysine, and cystine. A ration which fails to yield these in reasonable abundance cannot promote growth; but if the other (non-protein) dietary factors are suitable, increment of weight can promptly be brought about by the addition of these essential amino-acids. Buckner, Nollau, and Kastle² have attempted to test the validity of the conclusions just expressed, in a series of feeding experiments on young chicks, by using grain mixtures which they believed to exhibit a low and high lysine content respectively. The outcome was interesting in showing unmistakable differences in the growth of the birds in the two groups. For example, in one series the average change of weight per chick during the feeding period of 8 weeks was from 43 to 510 gm.; whereas on the ration supposedly low in lysine the increment

* The expenses of this investigation were shared by the Connecticut Agricultural Experiment Station and the Carnegie Institution of Washington, D. C.

¹ Osborne, T. B., and Mendel, L. B., *J. Biol. Chem.*, 1914, xvii, 325; 1916, xxv, 1.

² Buckner, G. D., Nollau, E. H., and Kastle, J. H., *Am. J. Physiol.*, 1916, xxxix, 162; *Kentucky Agric. Exp. Station, Bull.* 197, 1916.

was from 43 to 170 gm. in birds from the same lot, and kept under the same environmental conditions.

The rations employed by Kastle and his collaborators were complex, consisting of mixtures of various cereals and other seeds fed in part in the form of a mash and in part as a coarsely ground grain mixture. The authors concluded that "the marked differences shown by these two lots of chicks in rate of growth and development cannot be ascribed to the fat content of the two rations, but rather to differences in the amino-acid content of the two rations and in all probability to differences in the lysine content." The lysine yielded by these highly complex mixtures was estimated by the Van Slyke method of protein analysis. Of the nitrogen in the foods low in lysine about 0.7 per cent was stated to belong to this amino-acid; whereas the foods high in lysine contained three to five times as much.

Experience has shown that the results obtained by Nollau, who applied Van Slyke's method *directly* to feedingstuffs, are in some instances wholly erroneous.³ Thus a glance at the figures given by Nollau⁴ for the proportion of lysine shows numerous data inconsistent with our knowledge of the amino-acid content of the proteins of these food products, as determined directly by Kossel's method. For example, wheat gluten is represented as containing very much less lysine than the entire maize kernel, whereas in fact the reverse is the case.

Believing that the conclusion of Buckner, Nollau, and Kastle in respect to the relative amounts of lysine yielded by their foods was in the main correct, although unproved, we have concluded to attempt the application to the chick of the methods of feeding mixtures of more definitely known lysine content in the form of foods successfully employed by us in the case of albino rats and mice. Furthermore the rapid growth of this species furnishes a peculiarly advantageous opportunity to contrast dietaries of unlike nutrient quality.

The plan of the experiments was to compare the growth of chicks (Rhode Island Reds) fed on diets which, in one case contained "corn gluten," the mixed proteins of which yield about 1

³ See Grindley, H. S., and Slater, M. E., *J. Am. Chem. Soc.*, 1915, xxxvii, 2762. Hart, E. B., and Bentley, W. H., *J. Biol. Chem.*, 1915, xxii, 477.

⁴ Nollau, E. H., *J. Biol. Chem.*, 1915, xxi, 611.

per cent of lysine,⁵ and in the other case contained equal parts of "corn gluten" and lactalbumin, a protein yielding about 10 per cent of lysine.

Two types of food were employed. One, the fat food, identical with that furnished to our rats, was made in the form of a paste by grinding the ingredients together with a sufficient quantity of lard and butter fat; the other, the starch food, was made in the form of a coarse meal by substituting starch for a large proportion of the fat in the "fat food." The starch was first converted into a paste with boiling water, and then the other ingredients were stirred in. After being baked in an oven at 70-80°, the cakes were ground to a coarse meal. This product was similar, in texture as well as chemical composition, to a meal made by grinding grains. Both types of food were furnished at the same time, and each was eaten freely. The chickens exhibited varying preferences for essentially the same food ingredients supplied in these unlike physical textures. The composition of the mixtures was as follows:

	Corn gluten food		Corn gluten + lactalbumin food.	
	Starch food	Fat food	Starch food	Fat food.
	<i>per cent</i>	<i>per cent</i>	<i>per cent</i>	<i>per cent</i>
Corn gluten	38*	38*	19†	19†
Lactalbumin	0	0	9‡	9‡
"Protein-free milk"	28	28	28	28
Starch.	24	2	34	14
Butter fat	10	18	10	18
Lard	0	14	0	12

* Equal to 15.64 per cent protein ($N \times 6.25$).

† Equal to 7.82 per cent protein ($N \times 6.25$).

‡ Equal to 7.24 per cent protein ($N \times 6.25$).

The proximate composition of the "starch food" stated in the usual terms of a fodder analysis shows its chemical similarity to an ordinary high protein grain ration.

⁵ Our analysis of the special preparation of "corn gluten," for which we are indebted to Mr. H. C. Humphrey, showed it to contain 31.25 per cent of zein, which yields no lysine, and 13.69 per cent of maize glutelin, which yields 3 per cent of lysine. Compare Osborne, T. B., and Clapp, S. H., *Am. J. Physiol.*, 1908, *xx*, 477. From these data we conclude that the mixed protein of the "corn gluten" yields about 1 per cent of lysine.

Composition of the "Starch Food."

	Corn gluten food.	Corn gluten + lactalbumin food.
	<i>per cent</i>	<i>per cent</i>
N-free extract* (lactose, starch, etc.).....	68.1	69.6

Inorganic (ash).....	4.3	4.3
Crude fiber.....	0.0	0.0
	100.0	100.0

* This includes the unknown constituents of the "protein-free milk" together with citric acid and residues of protein.

These food mixtures therefore contain, aside from the protein ingredients, the essential substances including inorganic salts, fat-soluble and water-soluble hormones, which experience with rats has been shown to be required for perfect growth.

Four chicks, hatched on the same day in an incubator, were kept in pairs when they reached the age of 3 to 4 weeks. The wire cages in which they were placed during the first 3 weeks of the experimental period had bottoms about 18 x 12 inches, covered with dried sand. Small cloth hovers were provided. Each bird was then transferred to a separate cage, as it was noticed that the larger bird of each pair annoyed the smaller one to such an extent as to interfere with its growth. The new cages had bottoms 12 inches square which were covered daily with fresh sheets of blotting paper. After the birds had grown so large as to need more room (when about 80 days old) they were again transferred to cages twice as large.

The cages were kept in a well lighted and ventilated basement room, at a fairly uniform temperature of about 20°. During the first 3 weeks they were placed out of doors for a few hours when the weather was fine; and a small amount of clover, chickweed, and other green food was supplied. After the birds were about 7 weeks old they were kept continuously in the laboratory and no green food whatever was given them. During this time they acquired the habit of eating relatively large quantities of the blotting paper, which rendered their feces much more solid and seemed to be otherwise beneficial. Throughout the experiment

commercial chicken grit was supplied freely. During the course of the experiment one chicken of each pair died from causes not ascertained.

The weekly gains in weight of the two remaining chicks are indicated in the table below.

Body Weight in Gm. at Successive Weekly Periods.

Age.	Corn gluten food.	Corn gluten + lactalbumin food.
	Chick 3.	Chick 2.
days	gm.	gm.
22	106	80
28	118	101
35	112	129
42	105	163
49	115	197
56	122	221
63	129	267
70	142	310
77	153	363
Total gain in 55 days...	52	283

The photographs exhibit the unlike development and relative size of the chickens on these contrasted diets (Fig. 1).

The results here recorded are in agreement with our observations upon rats receiving similar diets. We thus see that corn gluten permits a very slight growth of chickens, as well as of rats, because it contains some maize glutelin—a protein which yields tryptophane as well as a little lysine.⁶ With chicks, as with rats, lactalbumin, rich in both tryptophane and lysine, is an efficient adjuvant to the proteins of corn gluten. The stunted Chick 3 exhibited no indications of malnutrition other than the failure to grow. When the bird was photographed at the age of 81 days its body, neck, and head were still covered with down and free from even rudimentary feathers. The wing feathers and a few on the side of the breast, which had begun to grow before

⁶ Osborne and Mendel, *J. Biol. Chem.*, 1914, xviii, 5. For the growth of rats on corn gluten see Osborne and Mendel, *ibid.*, 1914, xviii, 5, Chart V.

the beginning of the feeding experiment, continued to increase in size and appear in the photograph to cover a much larger part of the bird's body than was actually the case. The ruffled appearance of the feathers of Chicken 2 was largely caused by the frequent handling incident to weighing the bird daily during the experiment. *These observations corroborate, for the chick, the experience which we have previously published regarding the unlike value of different proteins in the nutrition of growth.*

In further accord with the observations on the growth of rats, cottonseed flour also forms a suitable adjuvant for the proteins of corn gluten, whereby in the presence of "protein-free milk," butter fat, etc., satisfactory increments of growth can be obtained. This is well shown by the records of two chicks from the same brood as that used in the previous experiments, fed on foods composed as follows.

Corn Gluten + Cottonseed Flour Food.

	Starch food.	Fat food
	<i>per cent</i>	<i>per cent</i>
Corn gluten.....	19.0*	19.0*
Cottonseed flour.....	20.5†	20.5†
"Protein-free milk".....	28.0	28.0
Starch.....	17.5-22.5	3.4
Butter fat.....	10.0	18.0
Lard.....	0.0	11.1
Paper.....	5.0-0.0	0 0

* Equal to 7.82 per cent protein ($N \times 6.25$) in the food.

† Equal to 9 per cent protein ($N \times 5.40$) in the food.

The increments of body weight were as follows.

Body Weight in Gm. at Successive Weekly Periods.

Age.	Corn gluten + cottonseed flour ration.	
	Chick 5.	Chick 6.
<i>days</i>	<i>gm.</i>	<i>gm.</i>
28	143	133
35	163	143
42	176	167
49	191	219
56	247	283
63	293	335
70	340	375
77	387	425
81	427	455
Total gain in 53 days...	284	322

One of these chicks at the age of 81 days had thus gained 322 gm. in a period of 53 days while at the same age Chick 3 on the corn gluten food had increased its weight only 44 gm. Photographs are shown at the age of 81 days after 53 days of experimental feeding (Fig. 2).

Our results confirm the conclusions drawn by Buckner, Nollau, and Kastle respecting the effect of foods high and low in lysine on the growth of chickens. Although their analyses cannot be depended upon to show with sufficient accuracy the content of lysine in their crude foods, it is probable, from what we know of the proteins in the seeds used by Buckner, Nollau, and Kastle, that the lysine content of the mixtures which they fed differed to a very considerable degree. In the case of our corn gluten food we know that its yield of lysine is very small, while that of the corn gluten + lactalbumin and of corn gluten + cottonseed flour is much greater. The assumption is therefore justified that chickens, as well as rats, require a sufficient amount of lysine in order to make normal growth and that this will doubtless be found true for other species.

Drummond⁷ has recently maintained that it is impossible to rear, to a satisfactory degree of development, young chicks kept under the artificial conditions prevailing in the laboratory in

⁷ Drummond, J. C., *Biochem. J.*, 1916, x, 77.

which he has worked. Further experience seems to us to be essential, in the light of the experiments of Buckner, Nollau, and Kastle, as well as our own, before a final conclusion in respect to the problem of the experimental feeding of young chickens can be promulgated. The rapid growth of this species renders chickens especially suitable for experiments on growth. It has therefore seemed worth while to determine the conditions under which, if possible, we can employ them for our future experiments.

EXPLANATION OF PLATE 1.

FIG. 1. Chicken 3, weight 162 gm. Chicken 2, weight 342 gm. Photograph showing two birds of the same hatching, at the age of 81 days. Chicken 3 received the corn gluten food, upon which it gained 52 gm in 55 days; Chicken 2, receiving an addition of lactalbumin in the ration, gained 283 gm. in the same period. The focal distance was the same for Figs. 1 and 2.

FIG. 2. Chicken 5, weight 427 gm. Chicken 6, weight 455 gm. Photograph showing two birds of the same hatching, at the age of 81 days. They received the corn gluten + cottonseed flour ratio, upon which they gained 284 gm. (5) and 322 gm. (6) respectively in 53 days.

THE EFFECTS OF TEMPERATURE AND FEVER UPON THE SYNTHESIS OF ETHEREAL SULFURIC AND UROCHLORALIC ACIDS IN THE ORGANISM.

By HIIZU ITO.

(From the Institute of Medical Chemistry of the Kyoto Imperial University,
Japan.)

(Received for publication, June 19, 1916.)

The discovery of the formation of hippuric acid from benzoic acid and glycocholic acid in an animal body has caused various investigations on relationships of organic compounds in the animal body. Various syntheses have been discovered, such as the formations of urea from carbonic acid and ammonia, of uramid acid, of ethereal sulfuric acid, and of conjugated glucuronic acids from their corresponding components.

I have taken up at the suggestion of Professor Araki the problem of the effects of temperature and fever upon the synthesis of ethereal sulfuric and urochloralic acids in the animal.

Salkowski's method of determining ethereal sulfuric acid was adopted in my experiments. As to the determination of urochloralic acid, urine was precipitated with neutral lead acetate, and the filtrate, which was obtained by the filtration of the upper transparent layer of the treated urine, was examined through the polariscope. Rabbits subjected to the experimentation were fed on "Tofukara"¹ in the cage of usual construction, which was always kept clean. In all the following experiments, the 24 hour urine of the rabbit was used.

Phenol.—For determination of the relation between the sum total of sulfuric and conjugated sulfuric acids of the urine, the 24 hour specimen which was obtained from a normal rabbit was carefully analyzed on the 1st day, as Tables I, III, and V show. On the 2nd day phenol was given to the animal. The ratio between the total of the sulfuric and the conjugated sulfuric

¹ The refuse of soy beans, first pressed and then cooked.

acids, which was found by the analysis of the urine on the 2nd day, was taken for the control. On the 3rd and 4th days the animal was fed no phenol. During this period the 24 hour urine was also analyzed to test whether the effect of phenol remained or not. That the phenol was entirely excreted on the treated days and the urine had returned to the normal condition was proved by comparing the results with those of the urine on the 1st day. On the 5th day, the same amount of phenol was given to the animal, which was subjected to high or low temperature or was attacked by fever on this day. The analyzed results of the above mentioned acids in the urine were compared with those of the control.

Chloral Hydrate.—Chloral hydrate was given to a rabbit on the 1st day. The rotation of urochloralic acid, which was found by the method already mentioned, was taken for the control. The rest of the treatment of the animal was the same as in the case of the phenol. Both series of experiments were conducted during all seasons except the summer.

I. Effect of Low Temperature.

According to Herter² the reduction of methylene blue in the tissues of an animal subjected to low temperature should be slower and less than normal. Since Quinquaud³ observed that a rabbit, when rapidly cooled, produced hyperglycemia and glycosuria, Araki⁴ and recently Fürth⁵ worked on the formation of the lactic acid in the animals which were subjected to very low temperature. Glaessner⁶ also found glucose and lactic acid in the urine of a man who committed suicide by drowning. According to Glaessner, the formation of the glucose and lactic acid was due to the insufficient supply of oxygen and the vigorous muscle exercise in the death struggle.

Judging from these facts it might be supposed that not only oxidation but other biochemical processes in the body of the cooled animal have been decreased. I thought, therefore, that

⁶ Glaessner, K., *Wien. klin. Woch.*, 1906, xix, 920; 1909, xxii, 919.

cold temperature might also affect the synthesis of ethereal sulfuric and urochloralic acids in the animal.

To cool the animal, as indicated in the following tables, I tied up its four legs and immersed it except its head in water at 8–15°C. For determining the body temperature of the cooled animal, a calibrated thermometer was always used. When the body temperature of the animal rose more than desired, it was cooled again in water as before. When the animal was in danger from very low body temperature, it was put a short time in warm water at 37–40°C., as Fürth directs, and recovered.

Examination of the results given above shows clearly that the synthesis was inhibited more as the duration of cooling was longer and the body temperature of the animal lower. It was obvious, therefore, that the synthetic process in the animal body was distinctly inhibited by the action of low temperature.

II. Effect of Fever.

Fever is a general reaction in an organism which disturbs the normal metabolic processes in the animal body. According to Leyden and Liebermeister,⁷ it has been asserted as typical of fever to increase the decomposition of animal matter. Senator⁸ stated that all substances in the body of a febrile animal do not undergo an equal decomposition, while it was recently proved by May and Stähelin⁹ that decomposition is uneven in the different periods of fever. Thus various writers reached various conclusions on this matter.

As regards the process of synthesis in fever, few studies, as far as I know, have been published. Weyl and Anrep¹⁰ proved that rabbits excrete less hippuric acid in fever than in the normal state. This was the reason why I took up the problem of the synthesis of ethereal sulfuric and urochloralic acids instead of hippuric acid in the same condition.

To make the animal febrile, "good" pus was injected under the skin of its back. The pus was roughly diluted with water according to its strength, before it was used. The amount for injection was also regulated by its strength, using a 10 cc. injection syringe. Sometimes one injection was enough to produce the desired condition, but generally two or three injections were needed. The animal which showed the symptom of diarrhea or whose temperature did not reach 40°C. was not used.

Experiment 5. Rabbit, 2,240 Gm.

We thus found that the synthesis of ethereal sulfuric and urochloralic acids was remarkably inhibited in the febrile animal, and the inhibition increased as the temperature was higher and the duration of the fevered condition was longer.

III. Effect of High Temperature.

In comparison with the effect of the febrile temperature on the destruction of proteins in the animal, the effect of high temperature artificially produced has been reported by many writers.¹¹ Unfortunately, however, agreement was reached only on the fact that differences exist between the effects of the fever and of artificially produced temperature.

In 1884 Aronson and Sachs raised the body temperature of a rabbit by means of a well known "*Waerme-stich*." I found, however, that it was not satisfactory for my purpose. Therefore I adopted the method of heating the animals in a well ventilated incubator. The animal was put into the incubator for 12 hours several times, with intervals of 15 to 60 minutes. The animal was taken out and cooled whenever it became overheated. The results are given in Tables V and VI.

From these results we may conclude that the high temperature, artificially produced in the animal also markedly prevented the synthetic process of the acids.

During these experiments the treated animal does not eat as much as usual, so it may be that the lack of food affects the results. But this may not be the case. For the decomposed products of proteins do not decrease even in the case of a 10 day starvation in man.¹² In the case of the rabbit, however, it takes

¹² Von Noorden, C., *Handb. path. Stoffwechsels*, Berlin, 2nd edition, 1906, i, 529.

some food even during the experimental period, or a strong rabbit loses no appetite at all. And, according to Fenyvessy,¹² conjugated glucuronic acids as camphoglucuronic acid and urochloralic acid are excreted as usual even at the time of starvation of a rabbit. For these reasons we may conclude that the lack of food does not affect the synthetic process of both acids in the treated animal.

From the results of the three series of experiments it may be seen that in each case the synthesis of both acids was remarkably inhibited; that is, high and low temperatures and fever act unfavorably on these syntheses. As to the mechanism through which temperature changes affect these processes, further investigations are required.

SUMMARY.

1. In rabbits in which abnormal temperatures are induced by chilling in water, warming in hot air, or creating fever by pus injections, the power of synthesizing ethereal sulfuric and urochloralic acids in the animal body is decreased.

2. The stronger the cooling and warming and the higher the fever, the more the conjugating function is prevented.

3. The lack of food in the experiments is not related to the decreased synthesis of the acids.

THE ACCUMULATION OF URIC ACID IN THE TISSUES DURING SUPPRESSION OF URINE.

By H. GIDEON WELLS.

(From the Otho S. A. Sprague Memorial Institute and the Department of Pathology of the University of Chicago, Chicago.)

(Received for publication, July 17, 1916.)

Among the items of evidence in favor of the view that the human organism possesses the ability to destroy uric acid is the observation of Schittenhelm and Wiener,¹ who reported the analysis of the tissues of a man who died after 6 days' complete suppression of urine, the result of bilateral thrombotic occlusion of the renal arteries. For analysis were used 1,385 gm. lung, 250 gm. heart, 250 gm. spleen, 1,785 gm. liver. First, 200 gm. samples of each were analyzed, and no uric acid was found. The rest of the tissues were then united and analyzed, and 10 mg. of uric acid obtained.

As control they cite analysis of tissues from a girl, 16 years old, dead from pernicious anemia. One portion analyzed consisted of 822 gm. liver, 602 gm. lung, 177 gm. heart, and 90 gm. spleen; the other consisted of 177 gm. kidney and 435 gm. intestine. From neither could any uric acid be isolated. Also tissues from a man with gout were analyzed; 10 mg. uric acid were recovered from the spleen and 15 mg. from the lungs, but none whatever from the liver, muscle, intestine, or kidneys.

These findings they interpret as indicating that uric acid is destroyed in the human body, for it is argued that since human liver can form uric acid from xanthine, and since it is known that the human organism can convert food purines into uric acid, there should be an appreciable retention of this uric acid and an accumulation in the tissues during 6 days total anuria.

"Die Versuche, besonders das Fehlen grösserer Harnsäuremengen in den Organen bei totaler Anurie, scheinen uns ein weiterer Beweis gegen

¹ Schittenhelm, A., and Wiener, K., *Z. exp. Med.*, 1914, iii, 397.

die Annahme der Unzerstörbarkeit der Harnsäure in menschlichen Organismus zu sein. Sie stehen im Einklang mit allen Analysen, welche von Organen überhaupt, auch menschlichen, angestellt wurden. Nie konnte man erhebliche Harnsäuremengen nachweisen."

While it must be admitted that the inference drawn is in harmony with the observation, nevertheless the failure to isolate uric acid from the tissues is by no means proof that destruction of uric acid has taken place in the body. Other possibilities must be considered. Uric acid that cannot be eliminated by the kidneys may be excreted by the bowel, which acts vicariously in renal deficiency. In the case of renal thrombosis described, no examination of the feces for uric acid was made, and even if such examination had disclosed the absence of uric acid from the feces, its excretion into the bowel would not be excluded, since bacterial decomposition might have removed it after being thus excreted.²

Furthermore, the failure of Schittenhelm and Wiener to isolate any considerable quantity of uric acid from the tissues after 6 days' anuria, even if there were no vicarious excretion, is not in the least surprising. A patient with anuria after a severe operation, as in their patient, is usually receiving or assimilating little nourishment and especially little containing nucleoproteins. Hence he is, as far as exogenous purine goes, practically on a purine-free diet, if not actually starved. The daily output of endogenous uric acid on a purine-free diet is given by some observers as about 200 to 300 mg., making a total for 6 days of 1.2 to 1.8 gm. According to the figures of Schittenhelm and Wiener their final analysis was made on 1,185 gm. lung, 50 gm. heart, 50 gm. spleen and 1,585 gm. liver, a total of 2,870 gm. If we assume that the retained uric acid is deposited equally in all tissues, we might expect to find in a man of average size, say 70 kilos, about 4 per cent of the total uric acid accumulation in the 2.87 kilos of tissue examined, or but 48 to 72 mg. But the evidence furnished by gout leads to the inference that uric acid is not uniformly distributed, but is deposited chiefly in the relatively avascular tissues, notably cartilage and periarticular fibrous tissues; rather than in the highly vascular tissues used in this analysis. We

² Siven, V. O., *Arch. ges. Physiol.*, 1914, clvii, 582.

certainly have no reason to expect retained uric acid to be deposited especially in the liver and lungs, and we have the facts of gout deposition to indicate that these tissues would not give a fair picture of the total retention of uric acid. Hence, recovery of 10 mg. uric acid from the viscera examined by the methods available for isolation of uric acid from larger quantities of admixed purines is by no means proof that uric acid has been destroyed by the tissues.

The statement that no uric acid can be isolated from tissues ("Nie konnte man erhebliche Harnsäuremengen nachweisen") is evidence that the methods are probably inadequate, rather than that there are not measurable amounts of uric acid present. The colorimetric method of Folin and Denis and its modifications indicate that human blood normally contains 2 to 3 mg. per 100 cc., and presumably the tissues are not free from uric acid if the blood contains this much. Fine,³ who discusses the work of Schittenhelm and Wiener, reports a series of analyses of viscera by this method, which indicate the presence of from 1.2 to 5 mg. of uric acid per 100 gm. of various tissues, either normal or from persons dying of disease not associated with nephritis. On the other hand, in three cases of uremia relatively large quantities of uric acid were indicated in the blood and tissues by the colorimetric method. In the blood the estimate was from 14.3 to 17.0 mg. uric acid per 100 gm., as contrasted with 0.7 mg. in each of three other non-nephritic cases. The various viscera contained from 7.3 to 18.0 mg. per 100 gm., and the skeletal muscle from 3.9 to 8.0 mg. Exudates showed figures comparable to the blood. In other cases of nephritis, blood drawn during life and examined colorimetrically has regularly shown high uric acid content, up to 27 mg. per 100 cc.⁴ If the colorimetric method is at all reliable, Fine's figures and those obtained by others show that when the kidneys are even partly out of function there does occur a noteworthy retention of uric acid in the blood and tissues. This fact is obviously not in harmony with the deductions drawn by Schittenhelm and Wiener.

For some time I have been waiting for an opportunity to secure suitable material from a case of complete anuria, in order to learn

³ Fine, M. S., *J. Biol. Chem.*, 1915, xxiii, 471.

⁴ Myers, V. C., and Fine, M. S., *Arch. Int. Med.*, 1916, xvii, 570.

whether uric acid can be isolated in greater quantities from the tissues in this condition than when urine is being secreted normally. This seemed necessary if the discrepancy between Schittenhelm's conclusions and the observations of Fine is to be explained. For the colorimetric method gives only presumptive evidence of uric acid, since, theoretically, the characteristic reaction might be given by other substances. Only actual isolation of the pure crystalline uric acid, with qualitative and quantitative evidence of its identity, can establish positively the presence of this substance in the tissues in considerable quantities. One case was finally obtained that permitted study of this matter.

A young woman, previously in good health, took about 17 grains of bichloride of mercury. Immediately thereafter she was taken to the Presbyterian Hospital, where she lived 9 days under close observation. During the entire time she excreted but 96 cc. of urine in spite of intravenous injections of alkaline salt solution (Fischer's solution) and hypertonic sugar solution, and renal decapsulation. Autopsy was performed less than 1 hour after death by Dr. B. O. Raulston, who kindly preserved the organs and blood for me on ice. The following tissues were analyzed for uric acid:

	gm.	
Blood.....	1,750	
Liver.....	1,350	
Intestine and stomach....	1,100	Emptied but not washed.
Mixed viscera.....	1,650	Consisting approximately of lungs (very edematous), 1,000 gm.; muscle, 250 gm.; spleen, 125 gm.; one kidney, 150 gm.; uterus and ovaries, 125 gm.

These tissues were ground, boiled in several liters of water, made faintly alkaline with NaOH, and almost immediately acidified slightly with acetic acid, to ensure solution of uric acid without destruction by the action of alkali. The coarser materials were strained off through cloth, and reextracted. The extracts were filtered hot and concentrated to about 1 liter each, and again filtered. As there was much gelatin in the extracts from the intestines and the mixed viscera, these were boiled with 7 per cent H_2SO_4 (to break up the colloids), then neutralized and filtered.

All four extracts were then analyzed for uric acid by precipitating the purines with copper according to the Krüger-Salomon method, and after freeing the purines with H_2S they were again precipitated with ammoniacal silver chloride. The silver salts were decomposed with HCl and the filtrates concentrated to about 100 cc. to let uric acid crystallize out. From the mixed viscera there separated out 0.097 gm. of typical uric acid crystals, giving the murexide test characteristically. A few crystals resembling uric acid also came out from the blood, but not enough to weigh, and this material was not removed from the solutions. The HCl was removed from the four solutions by evaporating first to a small volume, then to dryness after rediluting several times; the solutions were then made up to 200 cc. each, and the uric acid was estimated colorimetrically by Folin's phosphotungstic acid method, using uric acid dissolved in pyridine as the standard. The figures obtained indicated the presence in the solutions of the following amounts of uric acid.

	gm.	
Intestine.....	0.064	= 6 mg. per 100 gm.
Blood.....	0.044	= 2.5 " " 100 "
Liver.....	0.0135	= 1.0 " " 100 "
Mixed viscera.....	0.0225	(after removal of 0.097 gm. uric acid by crystallization.)

After making this determination, uric acid was sought directly by evaporating the purine solutions to dryness, extracting at room temperature with about 200 cc. of water to remove the more soluble materials. These water extracts gave no murexide test except that from the mixed viscera which gave a faint reaction.

The insoluble material was dried, dissolved in a minimum quantity of concentrated H_2SO_4 , filtered through dry asbestos, and diluted with 3 to 4 volumes of water. From the blood was obtained a crop of typical uric acid crystals, weighing 0.020 gm., which corresponded with 0.025 gm. in the original material when allowance was made for losses by sampling, etc., but without correction for solubility.

From the mixed viscera was obtained a mass of crystalline material, which on repurifying yielded 0.069 gm. uric acid. With the previous yield from this solution, in all 0.166 gm. pure uric acid crystals were obtained. This makes no allowance for losses

in the purification, which must have been considerable. All fractions had the typical crystalline form, and gave the murexide reaction typically. Analysis for nitrogen by Kjeldahl gave figures corresponding exactly to pure uric acid.

It will be noted that although the colorimetric estimation of this solution indicated the presence of 22.5 mg. uric acid, there were actually recovered 69 mg. From the blood, which was estimated colorimetrically as containing 44 mg. uric acid, there were recovered 25 mg.

From the intestine no uric acid could be recovered, although colorimetrically this solution was estimated as having the highest content, 64 mg., an amount that should have been recovered, at least in part. A small amount of guanine and xanthine were recovered, neither of which preparation gave either a murexide test or an appreciable reaction with the Folin reagent.

The liver extract also failed to yield any uric acid crystals, as might have been expected from the low content indicated colorimetrically (13.5 mg.). A small xanthine fraction was obtained which gave no murexide test, but did give a slight reaction with Folin's reagent.

Hence we have positively isolated considerable amounts of uric acid from the tissues of a girl suffering from total anuria for 9 days. Unquestionably the amounts recovered are considerably less than those actually present. That the uric acid recovered was not formed through postmortem changes is shown by the following facts: (1) The liver, which is the only human tissue that has been found capable of oxidizing xanthine to uric acid *in vitro*, contained the least uric acid. (2) Several other bodies examined at similar and longer periods after death have yielded little or no uric acid by the same methods. It may be suggested that the bichloride poisoning may have prevented destruction of uric acid. This seems improbable in view of the following facts: (1) The chief seat of uricolysis in mammals possessing this capacity is in the liver, which is relatively little affected by bichloride. (2) The liver of dogs and cats, killed by bichloride and other metallic poisons, destroys uric acid apparently as well as normal livers.⁵ (3) The liver loses none of its uri-

⁵ Unpublished observations.

colytic power in these animals even when the seat of the most severe fatty changes that can be produced experimentally.⁶

As controls the following analyses were made.

1. 1,240 gm. of blood were removed from the well preserved body of a man, who died of croupous pneumonia, and was autopsied 24 hours after death. There were the usual acute renal changes of pneumonia, but no chronic nephritis.

Analysis was conducted by the same method as above, but no uric acid could be isolated.

2. The body of a colored man who died of generalized tuberculosis, with very slight chronic interstitial nephritis, was autopsied 12 hours after death, and the following samples taken for analysis: blood, 379 gm., liver, 1,341 gm., other viscera, 2,173 gm. including intestine (cleaned and washed), lungs, spleen, diaphragm, kidneys, and stomach.

Analysis was conducted as before. From none of these materials could any recognizable uric acid be recovered by the most thorough examination and reexamination, although definite murexide reactions were given by all samples.

3. Autopsy 5 hours after death of a man dying of uncomplicated lobar pneumonia. For analysis used: blood, 790 gm., liver, 1,650 gm., viscera, 2,070 gm., including the uninvolved lung, kidneys, spleen, muscle, pancreas, bladder (washed thoroughly), prostate, testicles, esophagus, rectum (washed), and trachea.

No uric acid crystals could be obtained from the blood. By mistake the liver and viscera fractions became united. The insoluble purines were purified by Horbaczewski's method, and 26 mg. pure uric acid crystals were recovered after twice repurifying. This represented a considerably larger amount of uric acid actually present, since much must have been lost in the repeated repurification. The material gave the typical murexide reaction.

As pneumonia is a disease in which there occurs a high uric acid output⁷ because of the destruction of large amounts of leukocytes, and also is commonly accompanied by a decreased renal function, the successful demonstration of a small amount of uric acid in this material is not surprising.

4. The body of a man dying of a cerebral tumor (glioma) with practically no pathological changes elsewhere in the body was examined 9 hours after death. The following tissues were analyzed together: liver, 560 gm., spleen, 120 gm., kidney, 160 gm., intestine, 480 gm., lung, 340 gm.

Analysis by the same method as before yielded no crystalline uric acid, although a good murexide test was given by a portion of the purine solution.

⁶ Wells, H. G., *J. Exp. Med.*, 1910, xii, 607.

⁷ Kocher (*Deutsch. Arch. klin. Med.*, 1914, cxv, 380) found high figures for uric acid in the blood in pneumonia, up to 6.48 mg. per 100. cc.

The result of these analyses is definite. After practically complete suppression of urine for a period of 9 days, despite a practically purine-free diet and approximate fasting during that period, the tissues contained relatively large amounts of uric acid which could be readily isolated pure in quantities sufficient for analysis. In four other bodies of persons dying with either approximately normal or but slightly impaired renal function, little or no uric acid could be recovered by the same methods. It is therefore certain that after complete suppression of urine there may occur an accumulation of uric acid in the tissues not observed in the bodies of persons whose kidneys are functioning. Such an observation is not in favor of the hypothesis that the human body has the power of destroying uric acid, although it is by no means conclusive evidence to the contrary. It does, however, controvert the evidence advanced by Schittenhelm and Wiener that such retention of uric acid does not result from suppression of renal excretion.

THE FATE OF INGESTED STARCH IN PHLORHIZIN DIABETES.

BY FRANK A. CSONKA.

(From the Laboratory of Dr. J. P. McKelvy, Pittsburgh.)

(Received for publication, July 26, 1916.)

Glucose given *per os* to phlorhizinized dogs appears practically quantitatively in the urine as shown by Lusk and his collaborators.¹ Since starch is hydrolyzed before absorption to glucose, it was deemed of sufficient interest to determine the *quantitative* relationship existing between the glucose derived from starch and glucose derived from ingested glucose. Wheat flour and oatmeal were used in feeding; the amount of flour fed contained 16 to 20 gm. of starch.

The carbohydrates present in flour, in addition to starch, are cellulose and pentose; both of the latter, as shown by Lusk² and by Brasch,³ are not glycogenetic. In the following experiments it was found that more "extra glucose" was eliminated than could be accounted for by the amount of starch given; the excess could easily be explained by the presence of the protein in the flour.

EXPERIMENTAL PART.

Dogs were used in the experiments. After 2 days of fasting, the dogs were given daily subcutaneous injections for 6 days of 1.2 gm. of phlorhizin suspended in 10 cc. of olive oil. The experiment was performed on the 5th day of phlorhization. Periods of urine collection were separated by catheterization and washing out the bladder with 2.5 per cent boric acid solution. The food was prepared by mixing (wheat flour and oatmeal) each

¹ Reilly, F. H., Nolan, F. W., and Lusk, G., *Am. J. Physiol.*, 1898, i, 395. Csonka, F. A., *J. Biol. Chem.*, 1915, xx, 539.

² Lusk, G., *Am. J. Physiol.*, 1902, vi, p. xiii.

³ Brasch, W., *Z. Biol.*, 1908, i, 113.

with 200 cc. of water, warming for 30 minutes on the water bath, followed by cooling; it was eaten voluntarily by the animals. The analysis of the flour used in the experiments is given in the following table.

TABLE I.
In 100 Gm. of Material.

	Moisture.	Starch.	Nitrogen.	Protein N \times 6.25.
Wheat flour.....	12.14	75.18	1.94	12.12
Oatmeal.....	11.73	66.24	2.50	15.63

The moisture was determined *in vacuo* at 78°C. until a constant weight was obtained. The starch was determined by converting it to glucose by boiling with 1.5 per cent solution of HCl for 3 hours in a water bath. The nitrogen was estimated by the Kjeldahl method and the glucose by the Allihn method. The nitrogen and the glucose of the urine were determined respectively by the Kjeldahl and the Pavy methods; a polariscopic control was made for the latter. For the calculation of the "extra glucose" the method of Lusk was employed. The results of the feeding experiments are shown in Table II.

SUMMARY.

Starch given to completely phlorhizinized dogs is not utilized but is eliminated quantitatively in the urine as "extra glucose." There was not observed any difference in the failure to utilize the starch of wheat flour and the starch of oatmeal.

EXPERIMENTAL STUDIES ON CREATINE AND CREATININE.

V. PROTEIN FEEDING AND CREATINE ELIMINATION IN PANCREATIC DIABETES.*

By WILLIAM C. ROSE.

(From the Laboratories of Biological Chemistry of the University of Pennsylvania, Philadelphia, and of the University of Texas, Galveston.)

(Received for publication, July 10, 1916.)

The influence of diet on creatine and creatinine elimination has been the subject of numerous investigations in recent years. Among the earlier contributions were those of Cathcart^{1,2} in which it was shown that the elimination of creatine in man during inanition is inhibited by the ingestion of carbohydrates. This work was subsequently extended by Mendel and Rose,³ who advanced the theory that carbohydrate metabolism is in some way intimately associated with the *conversion* of creatine into creatinine. As a result of this interrelationship between the utilization of carbohydrates and the conversion of creatine into the anhydride, it was pointed out by Mendel and Rose that all conditions which interfere with the glycogenic function of the liver, or which render the organism unable to oxidize sugar, lead to the appearance of creatine in the urine. On the other hand, in man and rabbits, the oxidation of fat in the absence of carbohydrates has no influence on the creatine elimination during starvation.

* The earlier papers of this series were published as follows: Mendel, L. B., and Rose, W. C., *J. Biol. Chem.*, 1911-12, x, 213, 255. Rose, W. C., *ibid.*, 1911-12, x, 265; 1912, xii, 73. A preliminary report of this work was presented by title before the American Society of Biological Chemists, December, 1914.

¹ Cathcart, E. P., *Biochem. Z.*, 1907, vi, 109.

² Cathcart, *J. Physiol.*, 1909-10, xxxix, 311.

³ Mendel and Rose, *J. Biol. Chem.*, 1911-12, x, 213.

At about the same time that the paper of Mendel and Rose was published, Wolf and Österberg⁴ showed that in fasting dogs the feeding of protein likewise inhibits creatine elimination, and Wolf⁵ used this fact as a basis for attacking our theory regarding the importance of carbohydrates in creatine metabolism. The writer has repeated the experiments of Wolf and Österberg, and can corroborate their findings, despite the fact that the urines in some of their experiments were frequently alkaline, indicating the probability of decomposition. Protein feeding does inhibit the excretion of creatine in normal fasting dogs, but this fact does not necessarily invalidate the theory that carbohydrate utilization is an all important factor in creatine catabolism.⁶ It is a well known fact that over half the protein ingested may be converted into glucose in the body. It is possible that this glucose arising from protein in metabolism may be the inhibitory agent in creatine elimination.

In order to determine whether the disappearance of creatine from the urine in dogs, following the ingestion of protein, is due to carbohydrate arising in protein catabolism, it would only seem to be necessary to feed protein to diabetic animals. The sugar synthesized from protein would then be eliminated in the urine and could exert no inhibitory action on creatine excretion. If, under such conditions, creatine disappeared from the urine, it would be evident that the utilization of the sugar arising in metabolism from the protein of the diet is not the important factor in inhibiting creatine elimination in the normal animal. On the other hand, if the creatine output were not reduced to nil by protein feeding in the diabetic dog, proof would be conclusive that similar feeding in the normal fasting animal is effective because of this carbohydrate synthesized from protein. Such were the theoretical considerations which actuated the present investigation.

The experiments herein reported were begun during the spring of 1912. Unavoidable circumstances have delayed the continuance of the investigation. We realize that the experiments which we now present are rather limited in number, but since beginning

⁴ Wolf, C. G. L., and Österberg, E., *Biochem. Z.*, 1911, xxxv, 329.

⁵ Wolf, C. G. L., *J. Biol. Chem.*, 1911-12, x, 473.

⁶ It will be shown in the next paper that, contrary to the general belief, protein feeding in starving man likewise inhibits creatine elimination.

the work an interesting paper by Benedict and Österberg⁷ has appeared, the results of which have a direct bearing on the question at issue, and because of the similarity of our results to those of Benedict and Österberg, it seemed unnecessary to us to make a greater number of experiments.

EXPERIMENTAL PART AND DISCUSSION.

The investigation was made upon dogs rendered diabetic by complete extirpation of the pancreas. The operations were performed under ether anesthesia by Dr. J. E. Sweet of the University of Pennsylvania, and Dr. F. W. Aves of the University of Texas, to whom the writer acknowledges his indebtedness. The animals recovered rapidly from the effects of the incisions. In no case was there indication of infection in the region of the wound.

An attempt was made to feed freshly precipitated casein as the protein, but the animals refused to eat sufficient amounts of this material, and a diet of scrambled eggs, or ground beef heart washed free from creatine and creatinine was substituted. Both the egg and beef heart, though containing some fat, constituted satisfactory diets for the purpose of the investigation, since it has been repeatedly shown that fat has no inhibitory action on creatine elimination (Cathcart,² Mendel and Rose,³ and Wolf and Österberg⁴).

Total nitrogen was determined by the Kjeldahl-Gunning method, glucose by the rotation of polarized light before and after fermentation, and creatinine by the Folin method. In Experiments 1, 2, and 3, creatine was estimated by the autoclave method of Myers. It has been shown elsewhere⁸ that in the presence of considerable sugar the estimation of creatine by the Myers method gives too high results, and phosphoric acid was suggested as the dehydrating agent instead of hydrochloric acid, owing to the fact that the former does not lead to pigmentation. This method, which has been used by the writer in hundreds of determinations during the past four years, gives thoroughly satisfactory results in human urine provided the directions are followed, but, as pointed out in the original paper, is not applicable to the urine of dogs.

⁷ Benedict, S. R., and Österberg, E., *J. Biol. Chem.*, 1914, xviii, 195.

⁸ Rose, *J. Biol. Chem.*, 1912 xii, 73.

The figures representing urinary creatine in Experiments 1, 2, and 3 are probably somewhat too high, but, since the error is practically the same in all of the tabulated results of analyses, the data are not invalidated as pertaining to an increase or decrease in creatine excretion. In Experiment 4 the original water bath procedure of Folin was used for the conversion of creatine into creatinine. This method gives much less pigmentation in the presence of sugar than does the autoclave procedure. The creatine data in Experiment 4 should, therefore, be very near theoretical values.

The analytical results are shown in the tables. The figures do not represent exactly twenty-four hour excretions. Owing to the danger of injury to the wounds in removal of the animals from the cages and in catheterization, the urine which was voluntarily eliminated each day was taken for analysis. Hence, the absolute amounts of creatine and creatinine are less instructive than are the figures in the last columns representing the per cent of the total creatinine eliminated as creatine.

Experiment 1 is conclusive in showing that the feeding of large quantities of protein to diabetic dogs does not cause the disappearance of creatine from the urine as does similar feeding in normal fasting animals. Experiments 2 and 3 show the same fact, but are less conclusive owing to the short duration of the experiments. Animal 3 died on the 5th day after the operation, and Animal 4 refused to eat any form of protein after the 2nd day, thus necessitating the discontinuance of the experiment. Sufficient data are shown here, however, to prove our contention, especially in view of the results obtained by Benedict and Öster-

berg⁷ working on dogs with phlorhizin diabetes. These investigators found that by feeding sufficient protein, the nitrogen loss of the tissues could be completely balanced without causing the disappearance of creatine from the urine. Both the present paper and that of Benedict and Österberg furnish additional evidence that the "examples of the independence of the creatine excretion of the carbohydrate metabolism" described by Wolf⁸ are not as forceful as one would be led to believe. Undoubtedly, carbohydrate utilization is a most important factor in creatine metabolism.

It is interesting in this connection to observe the effect of protein feeding in Experiment 4. This animal was operated upon for the complete removal of the pancreas on Dec. 11. As will be seen from the protocols, the urine of the next day showed a G:N ratio of 2.5, and 58.5 per cent of the total creatinine in the form of creatine. Both the amount of creatine and the G:N ratio gradually diminished in this animal until on the last day of the experiment (Dec. 20) the G:N ratio was 1.1, and the per cent of the total creatinine eliminated as creatine had dropped to 16.7. On Dec. 20 the animal was returned to the pen. He lived for over a month after the experiment was discontinued, dying on Jan. 24

* The figures in this column represent the per cent of the total creatinine which was eliminated as creatine.

in a very emaciated condition. Autopsy showed the presence of a small amount of pancreatic tissue, which was identified by the microscopic examination of sections. The liver was fatty, and the upper portion of the duodenum was hypertrophied and hardened. Evidently the small amount of pancreatic tissue remaining in the abdominal cavity was sufficient to render the animal capable of oxidizing the major portion of the sugar arising from proteins, and the catabolism of this sugar was sufficient to diminish markedly the output of creatine.

Although the creatine output in completely depancreatized dogs is not reduced to zero by protein feeding, still *there is a perceptible decrease in the quantity excreted*. It will be observed that in Experiment 1 the per cent of the total creatinine eliminated as creatine fell from 66.7 on the 11th to 54.7 on the 17th. On the 18th and 19th, when the animal received no food, the creatine increased to 75.2 per cent of the total creatinine, and again fell the next day with feeding to 70.3 per cent. On the last day, although the animal received the largest ingestion of protein of the experiment, the creatine output increased to 77.0 per cent of the total creatinine. At first glance this appears to display a lack of uniformity in the data, but just preceding death in diabetes or starvation, the creatine cannot be reduced even by the ingestion of large quantities of carbohydrates.⁹ This is probably due to a greatly increased formation of creatine coincident with the excess tissue catabolism. Just as we have a premortal rise in the output of nitrogen, so there occurs a premortal increase in creatine elimination.

Aside from the difference in the behavior of the creatine output immediately preceding death, our animals always showed a slight decrease in the relative amounts of creatine excreted following protein feeding, but never were we able to induce the entire disappearance of creatine from the urine. In the shorter experiments (2 and 3) these facts are recorded just as in the experiment of greater duration. A glance at the data obtained by Benedict and Österberg⁷ shows that the ingestion of large amounts of protein by dogs with phlorhizin diabetes produces practically no diminution in the creatine output. We believe that the difference in the results obtained by these authors and by ourselves in regard to the creatine output is due entirely to the form of diabetes

⁹ Mendel and Rose, *J. Biol. Chem.*, 1911-12, x, 223, 229.

induced in the two series of experiments. The G:N ratio in phlorhizin diabetes as shown by Lusk is 3.65:1, and this is believed to represent the maximum sugar formation from protein. Phlorhizinized animals with such ratios are, therefore, quantitatively eliminating all glucose arising in protein catabolism. On the other hand, it is well known that the G:N ratio after extirpation of the pancreas is usually 2.8:1. Animals with such ratios are probably eliminating only about 77 per cent, and are utilizing 23 per cent of the glucose arising from protein. In an endeavor to explain these two types of ratios, Mandel and Lusk¹⁰ assumed the existence in blood of two forms of sugar which they termed α -colloid glucose and β -colloid glucose, the former being that amount of glucose represented by the ratio 2.8:1, and the latter the additional sugar eliminated when the ratio is 3.65:1. If this hypothesis is correct, the utilization of the β -glucose is probably responsible for the slight reduction in the output of creatine following protein feeding in pancreatic diabetes. We believe that the behavior of the creatine output following protein feeding in phlorhizin diabetes on the one hand, and after complete removal of the pancreas on the other, furnishes the most conclusive proof yet adduced of the interdependence of the creatine excretion and the carbohydrate metabolism.

CONCLUSIONS.

1. Protein feeding in dogs after complete extirpation of the pancreas does not lead to the disappearance of creatine from the urine as does similar feeding in normal fasting animals.

2. While protein feeding does not reduce the creatine output to zero, there is a slight decrease in the amount eliminated, which is attributed to the utilization of that amount of sugar represented by the difference between the ratios 3.65:1 and 2.8:1 (β -glucose of Mandel and Lusk).

3. The behavior of the creatine elimination in phlorhizin and pancreatic diabetes offers additional, and we believe conclusive proof of the dependence of the creatine elimination upon the carbohydrate utilization.

EXPERIMENTAL STUDIES ON CREATINE AND CREATININE.

VI. PROTEIN FEEDING AND CREATINE ELIMINATION IN FASTING MAN.*

By WILLIAM C. ROSE, FRANK W. DIMMITT, AND PAUL N. CHEATHAM.

(From the Laboratory of Biological Chemistry of the University of Texas, Galveston.)

(Received for publication, July 10, 1916.)

It has been generally accepted since the work of Cathcart¹ that the feeding of protein to fasting man exerts no influence on the output of creatine. A similar conclusion for starving rabbits was drawn from a limited number of experiments by Mendel and Rose.² In view of our observation and that of others³ concerning the marked reduction in urinary creatine in fasting dogs following the ingestion of protein, it seemed desirable to further investigate this question in man. If the explanation offered in a previous paper⁴ concerning the disappearance of creatine is correct, namely, that it is the glucose arising in protein catabolism which is responsible, then a similar reduction should occur in man under the same conditions. If one examines the paper of Cathcart,¹ it will be observed that the subjects of his experiments fasted for very short periods of time (usually 40 hours), and ingested the experimental diets over periods of correspondingly short duration. It is our experience that it is difficult to obtain thoroughly reliable data concerning fasting unless

* A preliminary report of this work was presented by title before the American Society of Biological Chemists, December, 1914.

⁴ Rose, W. C., *J. Biol. Chem.*, 1916, xxvi, 331.

the experiments are continued for several days. We have, therefore, subjected two individuals to periods of fasting for $3\frac{1}{2}$ to 4 days followed by periods of protein feeding for 3 to 4 days.

The experiments herein reported were made upon healthy men, one a graduate fellow in this department, and the other a student in the School of Medicine. The analytical procedures applied were the Kjeldahl-Gunning method for total nitrogen, and the original Folin methods for creatine and creatinine. The diet consisted of eggs, usually scrambled or boiled, but occasionally ingested in the raw state. Such a diet, of course, contains considerable fat, but it is universally admitted that the feeding of fat has no influence on creatine elimination in starvation.^{1, 2} The results of the experiments are detailed in Tables I and II.

It will be observed that in both experiments the feeding of large quantities of protein in the form of eggs very promptly reduced the creatine output. In Experiment 1, creatine entirely disappeared from the urine on the 3rd feeding day. In Experiment 2, the urine still contained 0.10 gm. of creatine expressed as creatinine on the 4th day of protein feeding, which amount was less than one-fourth that excreted before protein was ingested. The subject of the experiment had developed such a distaste for eggs that it was impossible for him to continue longer with this form of diet. If the carbohydrate arising from protein in catabolism is responsible for the conversion of creatine into creatinine and the consequent disappearance of the former from

the urine, then the ingestion of that amount of carbohydrate which would be synthesized by the organism from twenty-four eggs such as were ingested on the 21st should produce no greater reduction in creatine than did the eggs themselves. We have calculated this quantity basing our calculations on the generally accepted assumption that 58 per cent of the protein molecule may be transformed into glucose. If such be the case, twenty-four eggs would yield approximately 90 gm. of glucose. On the 22nd the subject in Experiment 2 received 90 gm. of carbohydrate in the form of sucrose. This was ingested in small amounts of about 5 to 6 gm. per hour throughout the day, in order to simulate as near as possible the conditions as regards available carbohydrate which were operative on the preceding day during the protein feeding. The result is shown in the table. It will be noted that the creatine output is practically identical (within the limits of accuracy of the analytical methods) with that of the 21st. Undoubtedly, if this individual had been able to ingest as many eggs as did the subject in Experiment 1, the creatine here also would have disappeared entirely from the urine.

It has been claimed by several investigators⁵ that the presence of acetone and diacetic acid in the urine in starvation and diabetes renders the estimation of creatine and creatinine inaccurate. We believe that the amounts of these bodies ordinarily present in starvation and diabetic urines are quite without effect on creatine-creatinine readings provided the urines are allowed to stand for at least 5 minutes after the addition of picric acid and alkali before diluting. Indeed, data were presented in a former paper by one of us⁶ in proof of this fact. Nevertheless, to avoid the possibility of a criticism of our creatine data by those who claim that all apparent creatine values are in reality due to errors in the method incident to the presence of diacetic acid,⁷ we have made a series of tests to demonstrate the influence of acetone and diacetic acid on creatinine readings. The urine of Nov. 30 in

⁵ Greenwald, I., *J. Biol. Chem.*, 1913, xiv, 87. Catheart, E. P., and Orr, J. B., *J. Physiol.*, 1914, xlviii, p. xxi. Krause, R. A., *J. Physiol.*, 1914, xlviii, p. xli.

⁷ Graham, G., and Poulton, E. P., *Proc. Roy. Soc., Series B*, 1914, lxxvii, 205.

Experiment 1 was analyzed for acetone bodies, and found to contain 0.87 gm. of acetone, and 1.53 gm. of diacetic acid. A normal urine containing no creatine was then diluted until analyses showed it to contain approximately the same amount of creatinine as did an equal volume of the experimental urine of the 30th. To portions of the normal urine were then added varying amounts of acetone and diacetic acid, and the prepared specimens analyzed for creatinine. The results are shown in Table III. It will be observed that in no case were there greater differences in the average creatinine readings than might occur in several analyses of the same urine in the absence of acetone bodies. *Without doubt figures representing creatine in our protocols are not erroneous values due to the presence of acetone or diacetic acid.*

TABLE III.

Experiment 3. Influence of Acetone Bodies on Creatinine Readings.

Acetone per 3,000 cc. of urine.	Diacetic acid per 3,000 cc. of urine.	Average creatinine readings.	Creatinine per 3,000 cc. of urine.
gm.	gm.	mm.	gm.
0	0	6.78	1.79
0.87	1.53	6.90	1.76
2.00	3.00	6.89	1.76
4.00	6.00	6.84	1.78

No explanation can as yet be offered for the observation of Mendel and Rose² that fasting rabbits as contrasted with fasting dogs and men display no diminution in the output of creatine following protein feeding. It can scarcely be a question of failure in protein utilization in rabbits, since the animals showed a markedly increased output of total nitrogen.⁸ On the other hand, one cannot assume that the transformation of amino-acids into sugar is more difficult for the herbivorous than for the carnivorous or omnivorous organism to accomplish. Further experiments are necessary to elucidate this point.

² Mendel and Rose, *J. Biol. Chem.*, 1911-12, x, 238, 239.

CONCLUSIONS.

1. Contrary to the generally accepted idea, protein feeding in starving man promptly reduces the creatine output to *nil*.

2. The amount of acetone bodies present in the urine during short fasts (3 to 4 days) is not sufficient to render the creatine-creatinine figures unreliable. Four times the quantities of acetone and diacetic acid eliminated in the present experiments were entirely without effect upon the creatinine readings.

EXPERIMENTAL STUDIES ON CREATINE AND CREATININE.

VII. THE FATE OF CREATINE AND CREATININE WHEN ADMINISTERED TO MAN.

By WILLIAM C. ROSE AND FRANK W. DIMMITT.

(From the Laboratories of Biological Chemistry of the University of Pennsylvania, Philadelphia, and of the University of Texas, Galveston.)

(Received for publication, July 10, 1916.)

It has been shown independently by Folin¹ and Klercker² that small amounts of creatine when added to the diet fail in part or entirely to reappear, while large amounts may lead to the presence of creatine in the urine. They were unable to demonstrate any conversion of creatine into creatinine, as was also Lefmann.³ Other investigators, notably van Hoogenhuyze and Verploegh,⁴ Pekelharing and van Hoogenhuyze,⁵ Foster and Fisher,⁶ Towles and Voegtlin,⁷ and Myers and Fine,^{8,9} are agreed that creatine introduced *per os* or parenterally is slightly converted into creatinine, and is largely excreted unchanged in the urine. By whatever avenue introduced creatine is never quantitatively recovered either unchanged or in the form of creatinine.

In explanation of the apparent disappearance of creatine, Folin¹ early suggested the possibility of its serving as a food and being

⁹ Myers and Fine, *J. Biol. Chem.*, 1915, xxi, 377.

stored. He states that, particularly in individuals on a low nitrogen diet, creatine in amounts less than 5 gm. is completely retained by the body. More recently Myers and Fine⁸ and Folin and Denis¹⁰ have adduced data indicating that ingested creatine is partly stored in the muscles. In the experiments of Myers and Fine, analyses of the muscle tissue showed that the slight increase in creatine content (about 5 per cent), following the subcutaneous administration of creatine, was quite insufficient to account for that which did not reappear in the urine. Other investigators (Nawiasky,¹¹ and Twort and Mellanby¹²) have attributed the apparent disappearance of creatine in feeding experiments to bacterial decomposition in the alimentary tract. Plimmer, Dick, and Lieb,¹³ in experiments in man, found that 2.5 gm. of creatine had to be given by mouth before any could be recovered in the urine. Without question creatine can be readily disintegrated by alimentary bacteria, but it seems unlikely that this is the sole explanation of its disappearance in feeding experiments in view of the fact that, when introduced parenterally, relatively large amounts still fail to reappear in the urine.

Feeding experiments with creatinine show that it is largely but not entirely eliminated unchanged in the urine. Towles and Voegtlin⁷ report that occasionally after administering creatinine to normal and Eck fistula dogs creatine also appeared in the urine, and this observation suggested the possibility of creatine dehydration being a reversible reaction in the animal organism. Myers and Fine,⁸ however, were unable to detect creatine in the urine following the administration of creatinine, but report that the creatine content of the muscles was increased. They state that, "In three experiments the creatine content was found to be about 6 per cent above the normal, an amount sufficient to account for the creatinine not eliminated by the kidneys."

It has been assumed by many investigators (Pekelharing,¹⁴ and Towles and Voegtlin⁷) that the disappearance of creatine in

feeding and injection experiments is due to partial destruction, possibly with the formation of urea. Indeed, Mendel and Rose¹⁵ suggested the possibility of urea formation some years ago, though no experimental data were adduced in support of this supposition. The work of Folin and Denis¹⁶ indicates that this idea is probably at fault. These investigators, from the results of analyses of blood and tissues following the absorption of creatine from a ligated segment of the gut, were able to demonstrate that none of the absorbed creatine was transformed into urea under the conditions of their experiments. The present paper furnishes additional data concerning the question of urea formation from creatine and creatinine.

EXPERIMENTAL PART.

The plan of the investigation was to feed excessively large doses of creatine and creatinine to individuals in nitrogen balance, and observe the effect on urinary composition, particularly with reference to the output of urea. The authors served as subjects for the experiments. The composition of the daily diets is shown in Tables I and II. Diet A was ingested by subject W. C. R. (Table III), and Diet B by subject F. W. D. (Tables IV and V).

The urines were always collected at the end of twenty-four hour periods, and were analyzed on the day of collection. Total nitrogen was estimated by the Kjeldahl-Gunning method, and creatine and creatinine by the original methods of Folin. In Experiment 1 ammonia nitrogen was estimated by the Folin method. In Experiments 2 and 3 urea nitrogen and ammonia nitrogen were estimated by the procedure of Van Slyke and Cullen.¹⁷ The creatine and creatinine used for feeding were prepared by the methods of S. R. Benedict.¹⁸ The creatine preparations gave no reaction with picric acid and alkali before hydrolysis, and uniformly showed a nitrogen content of within 0.07 per cent of the theoretical value. The creatinine preparation analyzed 100.2 per cent by the colorimetric method.

The results of the experiments are tabulated in Tables III to V. In Experiment 1 (Table III) it was impossible to follow the urea output owing to the fact that all of the methods for its estimation known at the time this experiment was made gave results much too high in the presence of large quantities of creatine. In Experiments 2 and 3, made more recently, the daily output of urea nitrogen is shown. Preliminary tests indicated that creatine and creatinine, even when present in 2 per cent concentrations, failed to interfere in the least with the accuracy of the Van Slyke-Cullen method.

¹⁷ Van Slyke, D. D., and Cullen, G. E., *J. Biol. Chem.*, 1914, xix, 211.

¹⁸ Benedict, S. R., *J. Biol. Chem.*, 1914, xviii, 183. The creatine used in Experiment 1 was prepared according to directions furnished by Professor Benedict in a private communication. The writer takes this opportunity of expressing his indebtedness for the use of this admirable method before its publication.

It will be observed (Tables IV and V) that the feeding of very large quantities of creatine (20 gm.) or creatinine (16 gm.) produces no appreciable effect upon the output of urea nitrogen. It is true that in both experiments, particularly after the administration of creatine, there was a slight rise in the output of urea nitrogen, but this rise was not sufficient to account for the creatine or creatinine which failed to reappear, or to indicate that urea is a catabolic product of these substances. It is more likely that the slight rise in urea output represents a partial deamination of creatine and creatinine through bacterial action in the gastro-intestinal tract rather than a specific catabolic function of the body cells. We believe that these data indicate that the theory accepted without direct proof by so many investigators, namely, that creatine and creatinine are destroyed in the body, is without foundation in fact. Our experiments corroborate the conclusions regarding urea formation from creatine reached by Folin and Denis¹⁶ using other methods of investigation. On the other hand we are unable to agree with these authors in their contention that creatine is not transformed into its anhydride in the animal organism. In both Experiment 1 and Experiment 2 a very perceptible rise in urinary creatinine was observed after the administration of large doses of creatine, and this rise was progressively greater as the dose of creatine was increased. In Experiment 1 the creatinine output increased from an average of 1.34 gm. per day in the fore-period to 1.83 gm. after 20 gm. of creatine were introduced, or an actual increase of 0.49 gm. In Experiment 2 the rise in output was from an average of 1.63 gm. to 1.93 gm., or an increase in actual amount of 0.30 gm. In view of the constancy in the creatinine output on a fixed diet, we believe these increases represent very decided ability on the part of the body to convert creatine into creatinine. Nor do we believe that these increases in urinary creatinine can be explained as suggested by Folin and Denis by a kind of saturation of the muscles with creatine, thereby resulting in the liberation of muscle creatinine. If such were the mechanism, it seems probable that the muscles would absorb creatine to the saturation point, and liberate the maximum amount of endogenous creatinine after doses of far less than 20 gm. of creatine. Judging by the output of unchanged substance, 5 gm. of creatine are considerably more

than the muscles are inclined to absorb. We believe that the only logical deduction from these data is that a portion of the exogenous creatine was transformed into creatinine and eliminated in the urine.

In Experiment 3 we were unable to detect any conversion of creatinine into creatine. Apparently the dehydration of creatine is not a reversible reaction in man. Approximately 80 per cent of the creatinine was recovered unchanged in the urine after the introduction of 16 gm. The remaining 20 per cent failed to reappear in any form.

CONCLUSIONS.

1. The ingestion of large doses (20 gm.) of creatine in man leads to a very perceptible increase (0.30 to 0.49 gm.) in the output of creatinine. This increase in urinary creatinine is attributed to a *conversion* of creatine into its anhydride, and not to an increase in the output of endogenous creatinine.

2. The ingestion of large doses (16 gm.) of creatinine is not followed by the appearance of creatine in the urine. This indicates that the reaction $\text{Creatine} \rightarrow \text{Creatinine} + \text{Water}$ is probably not a reversible one in the human organism.

3. No evidence was obtained indicating a transformation of creatine or creatinine into urea by the body cells. On the contrary, urea is probably not a catabolic product of these substances.

THE RELATION BETWEEN THE CONFIGURATION AND ROTATION OF EPIMERIC MONOCARBOXYLIC SUGAR ACIDS. II.*

BY P. A. LEVENE AND G. M. MEYER.

(From the Laboratories of The Rockefeller Institute for Medical Research.)

(Received for publication, July 5, 1916.)

The theoretical considerations that led up to the present work were discussed in a previous communication. On the ground of Hudson's investigations¹ one feels secure in accepting at least for the sugar series the validity of the superposition theory of the molecular optical rotation. On the basis of this assumption every pair of epimeric sugar acids may be graphically expressed as:

and the rotation of the radical

may be accepted $= \pm A$, and that of $R = \pm B$. Accepting M = the empirical specific rotation of one form, and N = that of the epimer, then the rotatory power of A may be calculated to be $\pm \frac{M - N}{2}$.

If this rule could be proven true for the known sugar acid it could serve for the determining of the structure of the higher syn-

* Levene, P. A., *J. Biol. Chem.*, 1915, xxiii, 145.

¹ Hudson, C. S., *J. Am. Chem. Soc.*, 1909, xxxi, 66; 1910, xxxii, 338; 1911, xxxiii, 405.

thetic sugars, and also for some natural sugars the structure of which is not completely worked out.

Furthermore, it was hoped also on the basis of Hudson's experience with glucosides and polysaccharides that radical A would be found to have a constant or nearly constant value for the salts of all acids with the same base. In a way this expectation was borne out by the values found by Nef² for the specific rotation of the brucine salts of xylonic and lyxonic acids, and of strychnine salts of the gluconic and mannonic, and of gulonic and idonic acids. For the first pair A was found to equal ± 4.43 , for the second ± 3.97 , and for the third ± 4.38 .

If this rule were found to hold for all known acids, it could be applied as a basis for purification of those acids the purity of which has as yet not been established.

In the hexonic acid series one pair of epimers is obtained in form of their crystalline lactones (gluconic and mannonic). The two corresponding parent substances are naturally occurring and crystalline sugars, glucose and mannose. The purity of these two need not be questioned. The same applies to galactonic acid. This crystallizes in the form of its lactone, which is derived from a crystalline sugar. Also gulonic and allonic acids crystallize in the form of lactones, the purity of which is certain. On the other hand, talonic (epimer to galactonic), idonic (epimer to gulonic), and altronic (epimer to allonic) have not been crystallized, and were obtained each from a mixture of the two epimers. The purity of these three acids is not certain.

At the outset of the work it was planned to purify these three acids until the values for A reached in each a constant value equal to that of the gluconic-mannonic pair. The difficulty of the task lay in the fact that it was not possible to find a mineral base which formed crystalline salts with all the acids. Because of this it was concluded to measure the rotation of the sodium salts. These could not be obtained in crystalline form; but it seemed an easy task to obtain these salts in solutions of known concentration. This actually was attained. But the sodium salts do not furnish a means of purification of the acids, and therefore there is no assurance that the solutions employed were pure in every instance.

² Nef, J. U., *Ann. Chem.*, 1914, cdi, 204.

On the other hand, it was found that brucine formed crystalline salts with all hexonic acids, and it seemed that these salts could serve the double purpose of purification and of measuring A for all acids under identical conditions. However, a difficulty was encountered here also in the fact that the brucine salts readily formed mixed crystals with brucine. Analytically the presence of brucine could not be detected. In fact there is reason to believe that brucine salts of the three non-crystalline acids have not yet been obtained in pure form. Notwithstanding this the general rule of the direction of the optical rotation of A was found to hold good for the brucine salts of all acids; namely, in acids having the same configuration of the α carbon atom as in *d*-gluconic the sign was plus, in those corresponding to *d*-mannonic it was minus. As regards the magnitude of the rotation it was found 4.6 for one pair and 3.38 for the second, and for the other three pairs the values were below these two. In the series of the sodium salts the direction of the rotation of A was found to obey the general law. The magnitude of the rotation, however, was not constant, perhaps for the same reason as in the series of brucine salts. Also for the pair of calcium salts of anhydrogluconic and anhydromannonic the rule of direction was found to hold.

The values recorded in this report are those of specific and not molecular rotation, since the work aimed principally to compare the rotatory power of salts of the same base.

Further work is in progress.

EXPERIMENTAL.

Gluconic acid was prepared by the oxidation of glucose with bromine. The acid was obtained as a syrup and converted into the calcium salt which was recrystallized several times from water. This purified calcium gluconate was used for the preparation of the sodium and brucine salts.

Sodium Gluconate.—This salt was not isolated, but a solution containing a calculated amount of salt as determined by titration was used for polarization.

2.6338 gm. of calcium gluconate were dissolved in a small amount of water and freed of calcium by a calculated quantity of oxalic acid. The filtrate was concentrated and then made up

358 Epimeric Monocarboxylic Sugar Acids. II

to 10 cc. in a volumetric flask. 2 cc. of this solution were removed and allowed to stand for 12 hours with an excess of 0.1 N NaOH. The uncombined NaOH was titrated back with 0.1 N hydrochloric acid, using phenolphthalein as indicator. To the remaining 8 cc. the calculated amount of 2 N NaOH was added and the solution again made up to 10 cc. This solution was employed for optical measurements.

By this procedure 2.08 gm. of sodium gluconate in 10 cc. gave

$$[\alpha]_D^{20} = \frac{+2.45^\circ \times 10}{1 \times 2.08} = +11.78^\circ$$

Brucine Gluconate.—Calcium was removed quantitatively from 5 gm. of calcium gluconate by means of oxalic acid and the solution of gluconic acid boiled with the calculated amount of brucine. The solution was then concentrated and the excess brucine removed with 98 per cent alcohol. The brucine gluconate was recrystallized out of 95 per cent alcohol until it reached constant rotatory power and till it gave correct analytical figures. Five recrystallizations were required for this purpose. The substance was dried at 100°, under diminished pressure. It melted at 155°.

0.1004 gm. substance gave 0.2175 gm. CO₂ and 0.0569 gm. H₂O.

$$[\alpha]_D^{20} = \frac{-0.41^\circ \times 1.975}{1 \times 0.0505 \times 1.005} = -15.95^\circ$$

d-Mannonic Acid.—This was prepared by the oxidation of *d*-mannose with bromine. The acid was readily converted into the lactone which was recrystallized several times out of boiling alcohol. The lactone was used for the preparation of the sodium and brucine salts.

Sodium Mannonate.—To 0.7850 gm. mannonic lactone, equivalent to 0.952 gm. sodium salt, 8.82 cc. 0.5 N sodium hydroxide were added and the solution was made up to 10 cc. in a normal volumetric flask.

$$[\alpha]_D^{20} = \frac{-0.84^\circ \times 10}{1 \times 0.952} = -8.82^\circ$$

Brucine Mannonate.—Several gm. of mannonic lactone dissolved in water were boiled for some time with a slight excess of brucine. The excess of brucine was removed with 98 per cent alcohol. The brucine salt was recrystallized three times out of 95 per cent alcohol. The salt was dried at 100° under diminished pressure. It melted at 212°.

0.1012 gm. substance gave 0.2199 gm. CO₂ and 0.0602 gm. H₂O.

	Calculated for C ₂₀ H ₂₁ N ₂ O ₁₁	Found:

$$[\alpha]_D^{20} = \frac{-0.67^\circ \times 2.5635}{1 \times 0.0663 \times 1.008} = -25.70^\circ$$

d-Gulonic Acid.—This was prepared from *d*-xylose by the addition of hydrocyanic acid. The product of the reaction was saponified with barium hydroxide and the barium removed with hydrogen sulfide. On concentrating this solution to a syrup gulonic lactone soon crystallizes. The lactone was purified by recrystallizing from 60 per cent alcohol, and was used for the preparation of the sodium and brucine salts.

Sodium Gulonate.—This was not isolated. The quantity of sodium hydroxide required to neutralize a definite quantity of gulonic lactone was determined on a separate sample. For optical measurements 0.7648 gm. gulonic lactone previously dried under diminished pressure at 100° was dissolved in a small quantity of water in a standardized 10 cc. volumetric flask, and 4.28 cc. *N* NaOH were added. The solution was allowed to stand for several hours before making up to volume.

0.7648 gm. gulonic lactone is equivalent to 0.938 gm. sodium gulonate. In a 1 dm. tube this solution gave $\alpha = +1.19^\circ$.

$$[\alpha]_D^{20} = \frac{+1.19^\circ \times 10}{1 \times 0.938} = +12.68^\circ$$

Brucine Gulonate.—This salt was prepared also from the lactone and was repeatedly recrystallized from 95 per cent alcohol until the physical properties remained constant. The salt was dried under diminished pressure at 100°; it then melted at 162–4°.

0.1008 gm. substance gave 0.2178 gm. CO₂ and 0.0596 gm. H₂O.

	Calculated for C ₂₂ H ₃₃ N ₂ O ₁₁ :	Found:
C.....	58.94	58.94
H.....	6.48	6.61

$$[\alpha]_D^{20} = \frac{-0.55^\circ \times 2.0646}{1 \times 0.0576 \times 1.006} = -19.59^\circ$$

Idonic Acid.—This was obtained from the mother liquors of the gulonic acid lactone. The syrup was shaken with five parts of 50 per cent sulfuric acid and two molecules of benzaldehyde.³ After some time the dibenzalidonate separated. This was filtered and washed with ice cold water and then cold alcohol until freed from acid, and then recrystallized from 95 per cent alcohol. The dibenzalidonate was then hydrolyzed with dilute sulfuric acid, the sulfuric acid removed quantitatively with barium hydroxide, and the solution of idonic acid concentrated to a syrup. This syrup of idonic acid was converted into the brucine salt.

Brucine Idonate.—This recrystallized from 95 per cent alcohol and, dried at 100° under diminished pressure, melted at 188°.

0.1050 gm. substance gave 0.2271 gm. CO₂ and 0.0619 gm. H₂O.

	Calculated for C ₂₂ H ₃₃ N ₂ O ₁₁ :	Found:
C.....	58.94	58.98
H.....	6.48	6.59

$$[\alpha]_D^{20} = \frac{-0.65^\circ \times 2.002}{1 \times 0.0502 \times 1.005} = -25.79^\circ$$

Sodium Idonate.—This was prepared from the above brucine salt but no attempt was made to isolate the substance. Brucine idonate dissolved in water was freed of brucine by means of barium hydroxide and the brucine removed by shaking out the solution with chloroform. The aqueous solution was completely freed of barium by sulfuric acid, and concentrated to a syrup. The absence of brucine was established by a qualitative test. This syrup was dissolved in a small quantity of water, transferred to a 10 cc. volumetric flask, and made up to that volume. A weighed portion of this solution was allowed to stand over night

³ Van Ekenstein, W. A., and Blanksma, J. J., *Rec. trav. chim. Pays-Bas*, 1908, xxvii, 1.

with an excess of 0.1 N sodium hydroxide and the removed sodium hydroxide titrated back with 0.1 N hydrochloric acid.

0.20213 gm. idonic acid solution required for neutralization 12.90 cc. 0.1 N NaOH.

Another quantity, 3.0306 gm., was neutralized with 0.97 cc. 2 N sodium hydroxide and made up to 5 cc. in a standard 5 cc. volumetric flask. This solution contained 0.4158 gm. sodium idonate and was used for optical measurements.

$$[\alpha]_D^{20} = \frac{-0.21^\circ \times 5.0}{1 \times 0.4158} = -2.52^\circ$$

Galactose.—This was oxidized with bromine, and the liquid, freed from bromine and hydrobromic acid, was concentrated to a syrup. To this syrup glacial acetic acid was added, and the mass soon solidified to the lactone. This was washed free from acetic acid and recrystallized from alcohol. A titration of this crystalline material dried under diminished pressure at 100° gave evidence of its being entirely lactone. It was allowed to stand 24 hours before titrating back with 0.1 N hydrochloric acid.

0.5970 gm. substance needed for neutralization 32.8 cc. 0.1 N NaOH. Required by calculation for lactone, 33.5 cc. 0.1 N NaOH; for acid, 30.4 cc. 0.1 N NaOH.

This lactone was used for the preparation of the sodium and brucine salts.

Sodium Galactonate.—0.8184 gm. of lactone, equivalent to 1.002 gm. sodium galactonate, dissolved in a small quantity of water in a 10 cc. volumetric flask, was allowed to stand with 9.2 cc. 0.5 N sodium hydroxide and then made up to volume.

$$[\alpha]_D^{20} = \frac{+0.04^\circ \times 10}{1 \times 1.002} = +0.40^\circ$$

Brucine Galactonate.—Several gm. of galactonic lactone dissolved in water were boiled with an excess of brucine for several hours. The liquid was concentrated to a small volume and the excess brucine removed with 98 per cent alcohol. The brucine salt was recrystallized repeatedly from 95 per cent alcohol until

362 Epimeric Monocarboxylic Sugar Acids. II

it possessed constant properties. Dried at 100° under diminished pressure it melted at 170°.

0.1012 gm. substance gave 0.2193 gm. CO₂ and 0.0607 gm. H₂O.

	Calculated for C ₂₂ H ₂₃ N ₇ O ₁₁	Found:
C.....	58.94	59.09
H.....	6.48	6.71

$$[\alpha]_D^{20} = \frac{-0.55^\circ \times 2.0144}{1 \times 0.0524 \times 1.006} = -21.01^\circ$$

Talonic Acid.—Galactonic acid was treated in an autoclave with pyridine at 160° for several hours, and the talonic acid as far as possible was separated from the galactonic acid by means of the cadmium and lead salts, and finally as the brucine salt. As Nef has already pointed out, the complete separation of galactonic and talonic acid is very difficult. The brucine salt, which was obtained by the above process was recrystallized several times from 95 per cent alcohol and dried at 100° under diminished pressure, had a melting point of 132°.

0.1016 gm. substance gave 0.2198 gm. CO₂ and 0.0589 gm. H₂O.

$$[\alpha]_D^{20} = \frac{-0.65^\circ \times 2.0423}{1 \times 0.0505 \times 1.005} = -26.15^\circ$$

d-Allonic Acid.—This was obtained from *d*-ribose by the addition of prussic acid. The substance was isolated as the lead salt, which was decomposed. On standing, the lactone crystallized.

Sodium Allonate.—This was prepared from the lactone. 0.4108 gm. lactone, equivalent to 0.501 gm. sodium salt, was dissolved in a small quantity of water in a 5 cc. volumetric flask and neutralized with 4.41 cc. 0.5 N NaOH.

$$[\alpha]_D^{20} = \frac{+0.43^\circ \times 5}{1 \times 0.501} = +4.30^\circ$$

Brucine Allonate.—This was prepared from the lactone. It was recrystallized from 95 per cent alcohol and dried under diminished pressure at 100°. It melted at 160°.

0.0994 gm. substance gave 0.2152 gm. CO₂ and 0.0570 gm. H₂O.

$$[\alpha]_D^{20} = \frac{-0.53^\circ \times 2.0277}{1 \times 0.0505} = -21.28^\circ$$

d-Altronic Acid.—This was the predominating substance in the preceding experiment. It was isolated as the calcium salt. The substance was repeatedly recrystallized from water. Allonic acid does not form a water-insoluble calcium salt.

Sodium Altronate.—1.1054 gm. calcium altronate were exactly freed of calcium with oxalic acid. The filtered solution was concentrated to a syrup. This syrup was dissolved in water in a 10 cc. standardized volumetric flask. 2 cc. of this solution were removed and titrated to sodium hydroxide. In this particular instance 2 cc. required 8.9 cc. 0.1 N NaOH. The remaining 8 cc. were now neutralized with the calculated amount of 2 N NaOH, made up to 10 cc., and allowed to stand for several hours. By calculation these 8 cc. contain 0.778 gm. sodium altronate. The rotation was taken in a 2 dm. tube.

$$[\alpha]_D^{20} = \frac{-0.63 \times 10}{2 \times 0.778} = -4.05^\circ$$

Brucine Altronate.—Calcium altronate, about 2.5 gm., was exactly freed of calcium and the filtrate boiled with brucine. The excess brucine was removed by shaking with chloroform in a separatory funnel, and the aqueous solution concentrated. The brucine salt was repeatedly recrystallized from 95 per cent alcohol and dried under diminished pressure at 100°. It melted at 158°.

0.1050 gm. substance gave 0.2263 gm. CO₂ and 0.0598 gm. H₂O.

$$[\alpha]_D^{25} = \frac{-0.22^\circ \times 2.0919}{1 \times 0.0541 \times 1.005} = -8.47^\circ$$

Chitic Acid, Calcium Salt.—Chitic acid was prepared from pure glucosaminic acid according to Fischer and Tiemann. It was isolated in the form of its calcium salt. The salt was once recrystallized out of water in the form of large colorless crystals.

The rotation of the calcium salt was as follows:

$$[\alpha]_D^{25} = \frac{+6.85^\circ \times 2.192}{1 \times 0.2042 \times 1.046} = +70.29^\circ$$

Brucine Chitarate.—2.0 gm. of the calcium salt were suspended in water and boiled with the theoretical amount of oxalic acid for $\frac{1}{2}$ hour. The filtrate was converted into the brucine salt in the

⁴ Fischer, E., and Tiemann, F., *Ber. chem. Ges.*, 1894, xxvii, 138.

usual way. The final product was recrystallized out of 95 per cent alcohol. It melted at 195°.

0.1002 gm. substance, dried under diminished pressure at the temperature of water vapor, gave 0.2246 gm. CO₂ and 0.0592 gm. H₂O.

	Calculated for C ₆ H ₁₀ O ₆ · C ₂₂ H ₂₂ N ₂ O ₄	Found:

THE OPTICAL ROTATION OF EPIMERIC α -HEXOSAMINIC ACIDS.

By P. A. LEVENE.

(From the Laboratories of The Rockefeller Institute for Medical Research.)

(Received for publication, July 5, 1916.)

The preceding paper¹ contains data showing that in each pair of hexonic acids the member which has the same configuration of the α -carbon atom, as *d*-gluconic acid, possesses either a higher dextrorotation or a lower levorotation than the epimer. From this it follows that in mixtures of unequal parts of two epimeric acids, the one which possesses a higher dextro- or a lower levorotation contains a higher proportion of the member having the configuration of the α -carbon atom, as in *d*-glucose. And still further, having the value of the rotation of one epimer in its pure form, and that of a mixture of the two, one may from these data conclude regarding the configuration of the α -carbon atom in each epimer. On the basis of this it was attempted to compare the rotation of epimeric α -hexosaminic acids with a view to finding an indication as to the respective positions of the amino group in each member of a given pair.

However, at present there are known only five α -hexosaminic acids, all of the *d* series, and since in each series eight acids of four pairs of epimers are possible, there exists evidently a lack of three amino-acids of the series. In order to fill in the gap the method of Fischer was resorted to, by which the heating of a sugar acid with pyridine leads to the formation of its epimer. True, it is not always an easy task to separate each member of the pair in pure state. Fortunately for the purpose of the present investigation this was not essential, as (this was pointed out above) the value of the rotatory power of one member in pure form and that of a mixture of the two furnish enough data for conclusions regarding the configuration of the α -carbon atom of each member of the pair.

¹ Levene, P. A., and Meyer, G. M., *J. Biol. Chem.*, 1916, **xxvi**, 355.

Unfortunately the supply of ribohexosaminic acid in our possession was not sufficient for the work, and the present observations are limited to three pairs of α -hexosaminic acids.

The mode of procedure was the following: An aqueous solution of the acid with pyridine was heated in sealed tubes at 100-105°C. for periods varying between 5 and 24 hours, and the resulting amino-acids were fractionated until one fraction was obtained of which the value of the optical rotation differed markedly from that of the original substance.

Table I contains the results of the observations.

TABLE I.

Acid.	[α] _D ²⁰	
	Original.	After treatment with pyridine.
I. <i>d</i> -Glucosaminic.....	-15.02°	+2.11°, +6.75°, +7.72°, +8.57°
II. <i>d</i> -Xylohexosaminic....	+11.77°	+15.47°
III. <i>d</i> -Chondrosaminic.....	-16.15°	- 4.83°
IV. <i>d</i> -Lyxohexosaminic....	-3.58°	-6.98°

Each of these four acids may have one of two possible configurations.

Accepting for the term "increase" in the value of the optical rotation any change from (-) towards (0) towards (+), one readily sees that any change in configuration (a) towards (b) must lead to an "increase," and *vice versa*.

The table shows for

Glucosaminic acid,	increase in rotation.
Xylohexosaminic acid,	increase in rotation.
Chondrosaminic acid,	" " "
Lyxohexosaminic acid,	fall " "

On the basis of this one would assign to

Glucosaminic acid	the configuration of	mannosaminic acid.
Xylohexosaminic (synthetic)	" " "	idosaminic "
Chondrosaminic	" " "	talosaminic "
Lyxohexosaminic (synthetic)	" " "	galactosaminic "

Of course, one must realize that for the present this evidence may be accepted only in the sense of an indication, which has to be substantiated by more direct methods. It is interesting in connection with this to compare the results of addition of prussic acid to pentoses and to the imines of pentoses. The predominating forms are:

Observations of Fischer and coworkers:

From arabinose.....	mannonic acid.
" xylose.....	gulonic "
" lyxose.....	galactonic "

Conclusions on the basis of present observations:

From arabinosimine.....	mannosaminic acid.
" xylosimine	idosaminic "
" lyxosimine.....	galactosaminic "

It is noteworthy that if these deductions were to prove true, it would appear that the configuration of the two amino sugars occurring in animal tissue are the epimeric forms of the two aldohexoses found in the tissues.

Efforts to solve the problem of the configuration of the α -carbon atom by methods more directly chemical are now in progress.

It is also contemplated to employ the pyridine method for preparation of the three missing hexosaminic acids in pure form.

EXPERIMENTAL PART.

Glucosaminic Acid. Experiment I.—2.5 gm. of glucosaminic acid were taken up in 30.0 cc. of water and 12 cc. of pyridine and heated in sealed tubes for 24 hours at 103–105°C. At the end of

the experiment the solution turned light brown, but remained perfectly clear and transparent. Four such experiments were combined. The solution was concentrated, decolorized, and acetone added until the solution began to crystallize on scratching the walls of the vessel with a glass rod. This precipitate on drying had $[\alpha]_D^{20} = -14.5^\circ$. The mother liquor was concentrated to very small volume and acetone was added until a small oily mass separated. On standing it crystallized. The substance was slightly colored, hence it was taken up in water and bone-blackened, dissolved in water, and acetone added until the substance began to crystallize. To afford a speedy reading, this was made in the Abderhalden tubes. The substance had the following composition.

0.0992 gm. substance gave 0.1347 gm. CO_2 and 0.0576 gm. H_2O .

	Calculated for $\text{C}_6\text{H}_{11}\text{NO}_5$	Found:
C.....	36.92	37.03
H.....	6.66	6.50

The rotation was as follows:²

$$[\alpha]_D^{20} = \frac{\text{Initial.}}{0.5 \times 0.2000} = +7.72^\circ \quad [\alpha]_D^{20} = \frac{\text{Equilibrium.}}{0.5 \times 0.2000} = +39.45^\circ$$

Experiment II.—10.0 gm. of glucosaminic acid were treated in four tubes as in Experiment I. At the end of the experiment the solution was found to be rather dark. Fractionation was carried out in the same manner as in Experiment I. The first fraction had $[\alpha]_D^{18} = -14.5^\circ$.

The rotation of the substance was the following.

$$[\alpha]_D^{18} = \frac{+0.05^\circ \times 4.2300}{0.5 \times 0.2000} = +2.11^\circ$$

Experiment III.—10.0 gm. of glucosaminic acid were taken up with 120.0 cc. of water and 50.0 cc. of pyridine were heated in sealed tubes at 103°C . for 12 hours. At the end of the experiment the solution turned brown. On cooling, some of the acid

² All rotations reported in this paper were taken in 2.5 per cent hydrochloric acid solution.

separated out in the tubes. Two experiments were combined. The quantity separated = 5.0 gm. Once recrystallized the substance had $[\alpha]_D^{25} = -15.0^\circ$. An attempt was made to concentrate the mother liquor under diminished pressure, but the solution foamed so badly that the experiment was interrupted and alcohol was added. A precipitate formed which was removed by filtration. To the filtrate more methyl alcohol and acetone were added. On standing at 0°C . for 24 hours a crystalline deposit formed.

The substance had the following rotations:

$$[\alpha]_D^{25} = \frac{+0.16^\circ \times 4.2228}{0.5 \times 0.2000} = +6.75^\circ$$

The substance was again recrystallized out of water and methyl alcohol, and then rotated as follows:

$$[\alpha]_D^{25} = \frac{+0.20^\circ \times 4.2866}{0.5 \times 0.2000} = +8.57^\circ$$

Xylohexosaminic Acid.—3.0 gm. of xylohexosaminic acid were taken up in 30.0 cc. of water and 12.0 cc. of pyridine and heated in sealed tubes at 105°C . for 24 hours. The solution was dark brown at the end of the experiment. It was concentrated under diminished pressure and precipitated with acetone. A precipitate formed which was partly crystalline and partly amorphous. It was taken up in water, decolorized, and on precipitation with acetone a colorless crystalline precipitate formed.

0.1016 gm. substance gave 0.1364 gm. CO_2 and 0.0618 gm. H_2O .

	Calculated for $\text{C}_6\text{H}_{13}\text{NO}_5$	Found:
C.....	36.92	36.61
H.....	6.66	6.82

The rotation was as follows:

$$[\alpha]_D^{25} = \frac{+0.24^\circ \times 4.8344}{0.5 \times 0.1500} = +15.47^\circ$$

Chondrosaminic Acid.—2.0 gm. of chondrosaminic acid were taken up in 20.0 cc. of water and 12.0 cc. of pyridine, and heated in sealed tubes at 100°C . for 5 hours. At the end of the experi-

ment the solution was dark brown and on cooling a small crystalline deposit was found in the tube. The mother liquor was filtered and concentrated under diminished pressure. A small crystalline deposit formed. All dissolved on warming, and acetone was added until the substance began to crystallize. The crystalline mass was dissolved in water, decolorized, and again made to crystallize by means of acetone.

0.1034 gm. substance gave 0.1380 gm. CO_2 and 0.0622 gm. H_2O .

	Calculated for $\text{C}_6\text{H}_{13}\text{NO}_5$	Found
C..	36.92	36.61
H.. ..	6.66	6.77

The rotation of the substance was as follows:

$$[\alpha]_D^{25} = \frac{\text{Initial}}{0.5 \times 0.1500} = -4.83^\circ \quad [\alpha]_D^{25} = \frac{\text{Equilibrium}}{0.5 \times 0.1500} = -23.86^\circ$$

Lyxohexosaminic Acid.—1.0 gm. of lyxohexosaminic acid was taken up in 10.0 cc. of water and 6.0 cc. of pyridine and heated in a sealed tube for 5 hours at 100°C . At the end of the experiment the solution had a dark brown color. It was concentrated to very small volume, taken up in methyl alcohol, and acetone added, until the substance began to crystallize. The sediment was then dissolved in hot water, decolorized with charcoal, filtered, and to the filtrate acetone was added until the substance began to crystallize.

It had the following composition.

0.0980 gm. substance gave 0.1304 gm. CO_2 and 0.0622 gm. H_2O .

	Calculated for $\text{C}_6\text{H}_{13}\text{NO}_5$	Found
C.....	36.92	36.36
H	6.66	7.07

The rotation of the substance was as follows:

$$[\alpha]_D^{25} = \frac{\text{Initial}}{0.5 \times 0.1500} = -7.65^\circ \quad [\alpha]_D^{25} = \frac{\text{Equilibrium}}{0.5 \times 0.1500} = -22.60^\circ$$

THE CONJUGATED SULFURIC ACID OF FUNIS MUCIN (MUCOITIN SULFURIC ACID). II.

By P. A. LEVENE AND J. LÓPEZ-SUÁREZ.

(From the Laboratories of The Rockefeller Institute for Medical Research.)

(Received for publication, July 20, 1916.)

The Whartonian jelly of the umbilical cord contains a substance resembling mucin or mucoids. The relation of the substance to other members of the group is not well known. Several workers have been engaged in the effort to furnish a solution to this problem. Obolensky¹ and Jernström² approached the subject by a study of the physical properties and ultimate composition of the molecule as a whole. In recent years Cavazzani³ followed the same plan of work. On the other hand, Young⁴ and Van Lier⁵ investigated into the presence of a conjugated sulfuric acid in the molecule of this substance, named by Young "funis mucin." Young failed to find evidence of the presence of a conjugated sulfuric acid. On the other hand, Van Lier, employing the method of Levene, isolated from funis mucin a substance resembling chondroitin sulfuric acid.

The present work was undertaken with a view to discovering the chemical relationship of this conjugated sulfuric acid to the other substances of this group.

The substance was isolated without any difficulty, following the procedure employed for the same task in course of the work on tendomucoid,⁶ chondromucoid,⁷ and on the mucin of the pig's

which brought down the conjugated sulfuric acid in form of a white flocculent precipitate. This was filtered, washed first by means of 50 per cent alcohol, and then by alcohol of progressively increasing concentration. The substance obtained in this manner was dissolved in a little water and the insoluble part removed by centrifugalization (in order to remove nucleic acid if present). The resulting clear solution was precipitated by means of alcohol.

The final substance was practically biuret-free. For analysis it was dried under diminished pressure over sulfuric acid at the temperature of water vapor.

0.1128 gm. substance gave 0.1352 gm. CO_2 and 0.0468 gm. H_2O .

0.1228 " " employed for Kjeldahl nitrogen estimation required for neutralization 3.97 cc. 0.1 N acid.

0.1242 gm. substance gave after fusion 0.0276 gm. BaSO_4 .

0.1245 " " " 0.0400 gm. BaSO_4 .

	Calculated for $\text{C}_{21}\text{H}_{16}\text{N}_4\text{S}_2\text{O}_{12}\text{Ba}_2$	Found:
C.....	27.80	32.65

Ba.....	22.70	21.67

Part II.—To the second part of the original filtrate a slight excess of barium carbonate was added and the mixture was placed on a boiling water bath for 5 hours. The concentrated solution was allowed to cool, and the precipitate of carbonate and coagulated protein removed by centrifugalization. The clear solution, which at this stage had the consistency of a syrup, was treated with glacial acetic acid as long as a precipitate formed. The precipitate was filtered on a suction funnel, washed first with acetic acid, and then with alcohol. It was then dissolved in water, and the solution made alkaline by means of a barium hydrate solution. Excess of reagent was precipitated by means of carbon dioxide, and the carbonate was removed by centrifugalization. The clear solution was then treated with 98 per cent alcohol as long as a precipitate formed. The substance was obtained in form of a white amorphous powder. It was biuret-free.

For analysis the substance was dried under diminished pressure over sulfuric acid at the temperature of water vapor.

0.1004 gm. substance gave 0.1312 gm. CO_2 and 0.0478 gm. H_2O .

0.1371 " " employed for Kjeldahl nitrogen estimation required for neutralization 3.50 cc. 0.1 N acid.

0.1247 gm. substance gave on fusion 0.0214 gm. BaSO_4 .

0.1315 " " " 0.0410 gm. BaSO_4 .

	Calculated for $\text{C}_{21}\text{H}_{12}\text{N}_2\text{S}_2\text{O}_{10}\text{Ba}_2$:	Found:
C.....	27.80	35.61
H.....	3.48	5.30
N.....	2.32	3.57
S.....	5.30	2.35
Ba.....	22.70	18.32

Hydrolysis of the Substance.—The material obtained for this experiment was prepared by the first of the two procedures described above. 50 cords were passed through a meat chopper, and then extracted with 1,500 cc. of a 3 per cent solution of sodium hydrate. The solution was treated exactly as the first sample. The yield was 15.0 gm. of the lead salt.

These 15.0 gm. were taken up in 100 cc. of 20 per cent hydrochloric acid solution, 1.5 gm. stannous chloride were added, and heated with a reflux condenser for 10 hours. The barium sulfate and pigment were removed by filtration, and the remaining clear solution was concentrated under diminished pressure to small volume. The residue was dissolved in 100 cc. of distilled water and lead and tin were removed by means of hydrogen sulfide. The filtrate from sulfides was freed from barium quantitatively and the clear solution was concentrated under diminished pressure to a syrup. A perfectly white crystalline deposit formed in the distilling flask. This was transferred on a suction funnel by means of methyl alcohol. It consisted of perfectly uniform crystals, in appearance unusual for glucosamine hydrochloride. Once recrystallized out of dilute alcohol it assumed the crystal form typical of glucosamine hydrochloride. Heated in a sealed capillary to a temperature of 220°C . it contracted slightly, turned dark, but did not melt.

Dried over sulfuric acid under diminished pressure the substance gave the following analytical results.

0.0314 gm. substance in Van Slyke micro apparatus gave 3.8 cc. N at 25° and 765 mm.

0.1577 gm. substance required 7.3 cc. 0.1N AgNO₃.

	Calculated for C ₆ H ₁₁ NO ₃ HCl:	Found:
N.....	6.50	6.45
Cl.....	16.45	16.41

The substance had the following rotation:

$$[\alpha]_D^{25} = \frac{\text{Initial.}}{0.5 \times 0.2008 \times 1.04} = \frac{4.08^\circ \times 2.1459}{0.5 \times 0.2008 \times 1.04} = 84.82^\circ \quad [\alpha]_D^{25} = \frac{\text{Equilibrium.}}{0.5 \times 0.2008 \times 1.04} = \frac{3.5^\circ \times 2.1459}{0.5 \times 0.2008 \times 1.04} = 71.94^\circ$$

CREATINE IN HUMAN MUSCLE.

By W. DENIS.

(From the Chemical Laboratory of the Massachusetts General Hospital,
Boston.)

(Received for publication, July 1, 1916.)

Although a fairly large number of observations concerning the creatine content of the muscles of the ordinary laboratory animals have been published¹ there is still a great scarcity of data concerning the creatine content of human muscle both normal and pathological; indeed the observations of Chisholm² constitute practically the only series of determinations made on this constituent of human muscle.

Chisholm (who appears to have been strongly influenced by the theory of Mellanby regarding the influence of the liver on creatine metabolism) concludes as a result of his examinations of the muscles from some thirty-six cases that the creatine content is reduced in cases of malignant disease, especially in those having growths in the liver; it is also reduced in chronic disease where there has been a marked loss in body weight. In cases of rapidly fatal acute disease and in chronic disease in which there is no loss of body weight the creatine content of the muscles is unaltered.

The determinations recorded in the following tables were made by Folin's method.³ In every case the right psoas muscle (free from fat and tendon) was used. The nitrogen determinations were made on an aliquot of the solution of hydrolyzed muscle used for the creatine determination, so that the creatine and the nitrogen figures represent the same 5 gm. sample of muscle.

As autopsies in this hospital are, in the great majority of cases, made not less than 6 hours after death, and frequently at a much

¹ Myers, V. C., and Fine, M. S., *J. Biol. Chem.*, 1913, xiv, 9. Folin, O., and Buckman, T. E., *J. Biol. Chem.*, 1914, xvii, 483.

² Chisholm, R. A., *Biochem. J.*, 1912, vi, 243.

³ Folin, O., *J. Biol. Chem.*, 1914, xvii, 475.

later period (the body being stored in a refrigerator kept at 0–2°C.), it was first necessary to determine whether this delay caused a loss in total muscle creatine.

As will be seen from the following figures storage for as long as 96 hours at –1° C. or as long as 18 hours at $\pm 20^{\circ}$ C. causes no decrease in the total creatine content of cat muscle.

Experiment I.—A cat was killed by chloroform, the muscles were quickly removed from the hind legs, and after removal of fat and tendons, were ground in a meat grinder. A number of 5 gm. portions of these muscles were then weighed out, two portions being immediately analyzed for creatine, and the remainder allowed to stand in stoppered flasks, some in the laboratory at a temperature of 20–25°C. and some in the refrigerator at –1–3°C. The results obtained are tabulated below.

Cat muscle, animal just killed	.0524	per cent creatine.
" " after 18 hrs. at 20–25°C.	0.524	" " "
" " " 48 " " 20–25°C.	0.228	" " "
" " " 48 " " 1–3°C.	0.524	" " "
" " " 96 " " 1–3°C.	0.524	" " "
" " " 168 " " 1–3°C.	0.475	" " "

Experiment II.—The muscles from the right hind leg of a rabbit which had been killed by a blow on the head gave, when analyzed half an hour after the death of the animal, 0.486 per cent of creatine. The muscles of the left hind leg of the same animal after storage at –1–3°C. for 28 hours without removal from the remainder of the body were found to contain 0.489 per cent of creatine.

In Table I are given the results obtained on the muscle of five individuals who may be fairly classed as "normal." It is un-

fortunate that the number of these cases is not greater but material of this class has been difficult to secure in quantity. From the results presented it would seem that the normal creatine content of human muscle varies between 360 and 400 mg. per 100 gm. of muscle, and that the creatine constitutes from 5.3 to 4.1 per cent of the total nitrogen. These figures are considerably higher than those presented by Chisholm for normal human muscle (300 mg. per 100 gm. muscle), a fact probably due to

the method of analysis employed by this investigator who used the technique recommended by Mellanby.

In Table II are given the results obtained on muscle from individuals who had suffered from chronic diseases, in most cases of long duration.

From the results presented in Table II it is evident that in many cases of chronic disease the muscle creatine differs in no way from that of normal individuals. In some cases, however, there is a marked decrease. On looking up the autopsy records and clinical histories of this latter class of cases it was found

that these individuals had almost without exception been ill for many months, and were in an extremely emaciated condition; Cases 21, 22, 23, 28, 31, 36, 37, 46, 47, and 56 (all showing markedly low creatine figures) were all especially noteworthy in this respect.

In Table III are given results obtained on the muscles of persons dying from acute diseases. Here again as in the case of the results presented in Table I we have in some cases practically normal figures whereas in others there is a marked reduction of the muscle creatine.

It has long been known that the creatine content of the muscles of children is lower than that of adults. It has therefore seemed best to collect all the results obtained on children's muscle in a separate table, IV. These figures warrant little comment on account of my inability to secure normal material as a control; Case 80 is the only one of this series which may be considered as normal.

SUMMARY.

Judging from the results presented above it would appear that the creatine content of the human psoas muscle of normal adults lies between 360 and 421 mg. per 100 gm. of muscle. In a series of determinations made on the psoas muscle of persons dying of various chronic diseases it was noted that in some cases the creatine content was reduced both absolutely and relatively. In most of these cases the patient had been in a cachectic condition for some weeks or months before death, and was greatly emaciated. In others the creatine values were not reduced. In the case of persons dying of acute diseases it was found that in many cases the muscle gave normal creatine figures; in others, more particularly those dying of septicemias, there was a marked reduction.

The fact that the muscle of children contains much less creatine than that of adults was confirmed.

These results would seem to lend confirmatory evidence to the theory concerning the interrelationship of "muscle creatine" and urinary creatinine in man (Shaffer, Myers and Fine). Shaffer has called attention to the fact that persons who have been ill for many months and are in a feeble and wasted condition have very low creatinine coefficients. As these patients become

convalescent and their "muscle tonus" increases the creatinine coefficient rises. No urinary examinations were made during the course of the present investigation but it is safe to assume that all of the feeble and emaciated patients whose muscle was found to possess such a low content in creatine had also an extremely low creatinine coefficient.

CONCERNING CERTAIN AROMATIC CONSTITUENTS OF URINE.

I. THE NON-PHENOLIC VOLATILE OILS OF COW URINE.

By R. J. ANDERSON.

(From the Chemical Laboratory of the New York Agricultural Experiment Station, Geneva.)

(Received for publication, July 24, 1916.)

INTRODUCTION.

It has been known for a long time that the distillates from acidified urine contain in addition to volatile acids, phenols, cresols, etc., certain non-phenolic or neutral volatile oils. The object of the present investigation was to isolate and identify these substances or at least to determine the properties and composition more closely than has been done heretofore of these terpene-like volatile oils obtainable from the urine of various animals. This paper deals with the substances isolated from the neutral oil, the so called "Städeler's Oel" and the products described by some authors as "Urogon" and "Urogol" obtained from cow urine.

This neutral oil was first observed and described by Städeler¹ as early as 1851 in his investigations regarding the volatile constituents of cow urine. He reports that the yellow oily liquid, finally obtained after distilling concentrated urine acidified with hydrochloric acid, was treated with strong potassium hydroxide which left a slight oily residue. This alkali-insoluble oil was removed by distilling the strongly alkaline liquid with steam.

The oil is described as having an agreeable odor resembling that of rosemary or origanum. It contained large quantities of nitrogen and it was soluble with a red color in concentrated sulfuric acid. The aqueous solution or suspension gave no color reaction with ferric chloride and it was not precipitated by basic lead acetate. The same author states that he had observed the occurrence of similar alkali-insoluble oils in the distillates from horse urine and human urine but in the latter it was present in very minute quantities.

¹ Städeler, G., *Ann. Chem.*, 1851, lxxvii, 17.

Various later investigators like Hoppe-Seyler,² Baumann,³ and Brieger⁴ have reported the occurrence of similar alkali-insoluble oils in the distillates from the urine of various animals. Of course we concern ourselves here only with the occurrence of these volatile oils in normal urine. The literature dealing with the metabolism and excretion of aromatic and terpene-like substances is so voluminous that it merely can be indicated in this place.⁵

Although several investigators, as mentioned above, had observed neutral alkali-insoluble oils in normal urines these substances had never been examined carefully or analyzed by anyone, so far as we are aware, until a few years ago when Mooser,⁶ to whose work reference must be made, reported a study of the aromatic substances of the urine. This author investigated particularly the neutral oil, the so called "Städeler's Oel." This oil was obtained from cow urine as follows: The concentrated urine was acidified with sulfuric acid and distilled until the distillate did not react with Millon's reagent. The distillates were united, mixed with calcium carbonate, and again subjected to distillation in an atmosphere of carbon dioxide. This second distillate was made *slightly* alkaline with potassium hydroxide and extracted with petroleum ether. The neutral oil isolated from this solution was washed several times with water and for further purification was treated in 20 gm. portions with 20 cc. of 10 per cent potassium hydroxide, again taken up in petroleum ether, and finally distilled in vacuum. The resulting distillate was a slightly yellow, strongly refractive oil of unpleasant odor which crystallized in needles when chilled in solid carbon dioxide. It was free from nitrogen and in composition it agreed with the formula C_7H_8O .

This oil, which the above author named "Urogon," is isomeric with cresol as it has the composition C_7H_8O , but for some reason it is believed to be different from cresol and is supposed to contain the $-CO-$ group although it did not give any of the reactions characteristic of the carbonyl group. In composition and properties it agrees closely with cresol but in spite of these facts it is considered to be a new and definite individual substance. In the hands of the above author this "Urogon," on treatment with potassium hydroxide, yielded two new compounds called "Urogol" and "Urogen."

When the crude oil "Urogon" was treated with sufficiently concentrated potassium hydroxide practically all of it went into solution with the exception of a small quantity of oil which had a pleasant terpene- or cymol-

⁴ Brieger, L., *Z. physiol. Chem.*, 1880, iv, 204.

⁵ Compare Neuberg, C., *Der Harn*, Berlin, 1911; and Hammarsten, O., *Lehrb. phys. Chem.*, Weisbaden, 8th edition, 1914, for references to the literature on the subject.

⁶ Mooser, W., *Z. physiol. Chem.*, 1909, lxi, 155.

like odor. From the alkaline solution a phenol was isolated which had the composition C_7H_8O and which is called "Urogol." Although this substance had all the properties of and the same composition as cresol, it is nevertheless believed to be different and isomeric with cresol. By the action of potassium hydroxide on "Urogon" there was also formed a hydrocarbon $C_{21}H_{42}$ called "Urogen."

This author apparently permitted the small quantity of oil of pleasant terpene-like odor which remained on treating "Urogon" with potassium hydroxide to escape his attention and examination. This is the more strange since this particular alkali-insoluble portion of the distillate is the oil referred to by Städeler.

The work of Mooser has been extended and augmented by Fricke⁷ who claims to have found the substance "Urogon" in the urine of most domestic animals as well as in human urine. It must be noted, however, that he felt satisfied in identifying "Urogon" by the smell and a few chemical reactions such as the red color developed with concentrated sulfuric acid and with Millon's reagent and that the substance reacted neutral to litmus and did not reduce Fehling's solution. In no case does he report the purification and analysis of any substance.

Neuberg⁸ mentions briefly that he did not succeed in preparing the substance "Urogon" in pure form and Neuberg and Czapski⁹ throw doubt upon the existence of any such substance. These authors do not report any investigation of urine for "Urogon" but base their doubt of its existence upon the fact that both phenol and cresol may be extracted from an alkaline aqueous solution with petroleum ether. For this reason they hold that the oil called "Urogon" by Mooser and Fricke as well as the "Urogol" of Mooser must have consisted chiefly of cresol.

As a result of our work we have found that the neutral oil called "Urogon" by Mooser is a mixture consisting principally of *p*-cresol, but containing a small percentage of a non-phenolic volatile oil having the composition $C_{10}H_{16}O$ and consequently isomeric with camphor. The various details of the isolation and purification will be fully described in the experimental part.

The phenol called "Urogol" by Mooser obtained from the "Urogon" by treatment with concentrated alkali possesses all the properties of *p*-cresol and yields derivatives identical with those of *p*-cresol; hence we do not believe that there is any room for doubt regarding the identity of these substances.

The reason why cresol occurs in the residual neutral oil is due to the fact, as pointed out by Neuberg and Czapski,⁹ that cresol

⁷ Fricke, E., *Arch. ges. Physiol.*, 1914, clvi, 225.

⁸ Neuberg, *Der Harn*, Berlin, 1911, i, 518.

⁹ Neuberg, C., and Czapski, L., *Biochem. Z.*, 1914, lxxvii, 28.

In this connection the experiments described by Fromm, ¹⁰ and Clemens,¹¹ "Über das Verhalten des Camphens im Thierkörper," are interesting. These authors after feeding camphene to rabbits isolated a conjugated glucuronic acid from the urine which on distilling with sulfuric acid gave a volatile oil of the composition $C_{10}H_{16}O$. After purifying over the bisulfite compound this substance crystallized and was found to be identical with camphenilan aldehyde. They believed, therefore, that camphene must be oxidized in the body to a dihydroxyl compound which is eliminated as a conjugated glucuronic acid. On cleavage the dihydroxyl compound easily splits off water giving the aldehyde.

It is probable that the oil $C_{10}H_{16}O$ which we have isolated from cow urine had been eliminated in the same way and that the hydroxyl groups had been split off during the distillation with the sulfuric acid. The above oil is present in urine in very small quantity; the amount at our disposal did not permit of a complete investigation, and we have not been able to identify the substance.

¹⁰ Compare the works of Schmiedeberg, O., and Meyer, H., *Z. physiol. Chem.*, 1879, iii, 422; Sundvik, E., *Akad. Afhandling*, Helsingfors, 1886; Fromm, E., and Hildebrandt, H., *Z. Physiol. Chem.*, 1901, xxxiii, 579.

¹¹ Fromm, E., Hildebrandt, H., and Clemens, P., *Z. Physiol. Chem.*, 1902-03, xxxvii, 183.

It would seem, however, that the above oil is not a constant metabolic product, since the oil isolated from the urine during the winter, although it had the same composition, did not give a crystalline semicarbazone. Evidently, therefore, the nature of the non-phenolic oils excreted in the urine depends upon the nature of the terpene-like substances contained in the feed.

EXPERIMENTAL.

Mixed urine from a herd of cows was collected during the summer while the animals were part of the time in pasture. The fresh urine was concentrated to about one-eighth of its volume and then strongly acidified with sulfuric acid and distilled with steam until no more oil went over. The distillate was made strongly alkaline with sodium hydroxide and extracted with several portions of ether. The ethereal solution was further shaken for some time with dilute sodium hydroxide and after that with dilute sulfuric acid and finally washed with water. After drying with sodium sulfate the ether was evaporated and the residue distilled in vacuum. From 127 liters of urine 38.75 gm. of oil were obtained.

The light yellow oil was of neutral reaction on litmus paper and it possessed an extremely unpleasant penetrating odor which resembled the peculiar smell of a cow stable. It contained neither nitrogen nor sulfur. With concentrated nitric acid it reacted with great violence. When shaken with concentrated sodium or potassium hydroxide the disgusting odor disappeared and an agreeable terpene-like odor resulted. Bromine was readily absorbed with liberation of hydrobromic acid. It was soluble in all proportions in all the organic solvents and in concentrated sulfuric acid it dissolved with a red color. It was insoluble in concentrated hydrochloric acid or in ammonia. It did not reduce Fehling's solution but an ammoniacal solution of silver nitrate was reduced on heating.

On analysis the following result was obtained.

0.1988 gm. of substance gave 0.1365 gm. H_2O and 0.5630 gm. CO_2 .

Found: C = 77.24; H = 7.68 per cent.

Molecular weight determinations were made by the freezing point method using benzene as solvent and the following figures obtained.

	1	2
Weight of substance, gm.	0 2042	0 2364
" " benzene, gm	16 3229	15 1615
Depression	0 524°	0 661°
Mol. wt	117	115

The properties, reactions, composition and molecular weight correspond with those described by Mooser⁶ for the neutral oil from cow urine to which he gave the name "Urogon."

This oil, however, was not a homogeneous substance but could be separated into two fractions. After fractionating in high vacuum three times the first portion of the final distillate which embraced about 75 per cent of the total oil went over between 68–69° at 0.5 mm. pressure.

The residues from these distillations were reserved for further examination.

The product obtained, as above, was a practically colorless oil slightly heavier than water, and it had a distinctly phenolic but not unpleasant odor. Its aqueous solution gave a fine blue coloration with ferric chloride. With concentrated nitric acid it reacted with great violence and it dissolved in concentrated sulfuric acid with a red color. It was completely soluble in concentrated sodium or potassium hydroxide. When cooled in a freezing mixture of ice and salt it crystallized to a white solid mass. It gave the following result on analysis.

0 1852 gm. of substance gave 0 1263 gm. H₂O and 0 5244 gm. CO₂
 Found: C = 77 22; H = 7 63 per cent

The substance crystallized, as already mentioned, when it was cooled in a freezing mixture. When some of these crystals were introduced into the oil previously cooled to 13° practically the whole substance changed slowly into massive prisms. For the removal of traces of adhering oil the crystals were pressed between filter paper. There remained a snow-white mass of crystals which melted at 21°, and it boiled at atmospheric pressure at 198.5° (uncorrected). This crystalline substance was analyzed.

0 1457 gm. of substance gave 0 0967 gm H₂O and 0 4140 gm. CO₂
 Found: C = 77 49; H = 7 42 per cent.
 For cresol, C₇H₈O = 108. Calculated: C = 77 77; H = 7 40 per cent

It will be noticed from the above analyses that both the oil and the crystalline substance have the same composition. The substance is identical with the "Urogol" of Mooser but it is evident from the above analyses that it is also either identical or isomeric with cresol. Despite the low melting point we believe that it is nearly pure *p*-cresol for the reasons to be shown below.

Its solubility in concentrated alkali and its blue coloration with ferric chloride indicated its phenolic nature and it gave no reactions characteristic of aldehyde or ketone groups; *i.e.*, it gave no crystalline derivatives with phenylhydrazine, sodium bisulfite, hydroxylamine, or semicarbazide hydrochlorides.

It gave, however, two bromine substitution products corresponding to mono- and dibrom cresol. The dibrom compound had the same melting point as given for dibrom *p*-cresol.

Bromination of the Substance.

Preparation of the Monobrom Derivative.—The oil, 2.7 gm. (one molecule), was dissolved in 50 cc. of chloroform and to it were added 4 gm. (one molecule) of bromine dissolved in 25 cc. of chloroform. The bromine color disappeared immediately and much hydrobromic acid was given off. The chloroform solution was washed several times with water to remove the hydrobromic acid and then dried with sodium sulfate and the chloroform distilled off. An oily residue remained of intensely penetrating odor. It did not solidify in a freezing mixture. In vacuum at 3 mm. pressure it boiled at 80–81°. It was obtained as a colorless, highly refractive, heavy oil which rapidly darkened when exposed to the light. The yield was 3.4 gm. which corresponds to 74 per cent of monobrom derivative. The substance was analyzed at once.

- | | | | | | |
|----|-------------------------|------|-----------------------------|-------|------------------------------|
| 1. | 0.1586 gm. of substance | gave | 0.0530 gm. H ₂ O | and | 0.2609 gm. CO ₂ . |
| 2. | 0.1615 " " " | " | 0.0591 " " | " | 0.2688 " " |
| | 0.1825 " " " | " | 0.1817 " " | AgBr. | |

Found: 1. C = 44.86; H = 3.73; Br = 42.37 per cent.

2. C = 45.39; H = 4.09 per cent.

For monobrom cresol, C₇H₇BrO = 186.9.

Calculated: C = 44.94; H = 3.74; Br = 42.75 per cent.

Preparation of the Dibrom Derivative.—This was easily formed by the action of 4 gm. (two molecules) of bromine upon 1.35

gm. (one molecule) of the oil in chloroform solution. The bromine color disappeared immediately until about one-half of the bromine had been added, but after that more slowly. After standing for 3 hours at room temperature the bromine color had disappeared. The hydrobromic acid was then washed out with water and the chloroform solution dried with sodium sulfate. After evaporating the chloroform in vacuum there remained a light yellow colored oil which immediately crystallized when placed in a freezing mixture.

The crystals were extremely soluble in all of the ordinary organic solvents but insoluble in water and it was found impossible to recrystallize the substance from any of the above solvents. On the spontaneous evaporation of the solvents, however, the substance separated in crystalline form, some of the crystals being delicate colorless needles or prisms over an inch long.

The substance was finally recrystallized as follows: It was dissolved in chloroform and placed in an open crystallizing dish and the chloroform evaporated in a vacuum desiccator. The crystalline substance which remained was separated mechanically from the dark colored portion and recrystallized in the same manner. From this second recrystallization there were obtained 1.7 gm. of practically colorless crystals. When slowly heated the substance melted between 48–49° (uncorrected). According to Beilstein the crystalline dibrom *p*-cresol melts at 48–49°.

A larger quantity of the substance was prepared and recrystallized from ligroin. This also melted between 48–49°. The following result was obtained on analysis.

0.2070 gm. of substance gave 0.0433 gm. H_2O and 0.2382 gm. CO_2 .

0.1702 " " " " 0.2425 " AgBr.

Found: C = 31.38; H = 2.34; Br = 60.63 per cent.

For dibrom cresol, $C_7H_6Br_2O$ = 265.8.

Calculated: C = 31.60; H = 2.25; Br = 60.12 per cent.

Judging by melting point and composition the above crystalline substance is pure dibrom *p*-cresol.

In order to determine whether the substance would take up more than two atoms of bromine the following experiment was carried out: To 1.35 gm. (one molecule) of the oil in 50 cc. of chloroform were added 6 gm. (three molecules) of bromine in

25 cc. of chloroform. This was allowed to stand for 3 hours at room temperature. The color at the end of this time was deep brown, showing the presence of bromine. The chloroform was washed with water to take up the hydrobromic acid and the excess of bromine was removed by shaking with a solution of sodium bisulfite. The chloroform solution was again washed with water and finally dried with sodium sulfate. After evaporating the chloroform the oily residue crystallized on cooling in ice water. After dissolving in chloroform and transferring to a tared crystallizing dish the chloroform was evaporated at room temperature in a vacuum desiccator. After drying in vacuum over sulfuric acid the crystals weighed 3.4 gm. which is equal to about 100 per cent yield of the dibrom *p*-cresol. This behavior of taking up only two atoms of bromine under ordinary conditions is characteristic of *o*- and *p*-cresol while the *m*-cresol under like conditions takes up three atoms of bromine.¹²

It would seem from the properties and composition of the above oil and particularly those of the bromine derivatives just described that the substance in question is cresol and apparently nearly pure *p*-cresol. The substance is also by its method of preparation and its properties identical with the product named "Urogol" by Mooser. Evidently, therefore, this designation is superfluous since the substance possesses all the properties and reactions of *p*-cresol.

Examination of the Oily Residues Remaining after Isolating the p-Cresol.

The residues were united and repeatedly fractionated in vacuum, when there was finally obtained a small amount of a light yellow oil of agreeable terpene-like odor. It did not react with cold concentrated nitric acid but the oil turned reddish, then violet, and finally deep purple in color. On heating with concentrated nitric acid it dissolved without any visible reaction and on diluting with water a cloudy solution resulted. In concentrated sulfuric acid it dissolves with a red color. It is insoluble in concentrated sodium or potassium hydroxide even on boiling but the oil turns dark in color. After shaking with water the aqueous

¹² Meyer, V., and Jacobson, P., *Lehrb. organ. Chem.*, 1902, ii, pt. i, 379.

solution gives no reaction with ferric chloride. It is very soluble in all of the ordinary organic solvents but insoluble in water. The aqueous suspension of the oil reduces ammoniacal silver nitrate on heating. Potassium permanganate solution is decolorized when added to the oil suspended in water. In chloroform solution bromine is absorbed at once with liberation of hydrobromic acid. The oil went over at 102° at about 1 mm. pressure. On analysis the following result was obtained. .

0.1538 gm. of substance gave 0.1490 gm. H_2O and 0.4413 gm. CO_2 .
Found: C = 78.25; H = 10.84 per cent.

The oil was dissolved in a little ether and thoroughly shaken with 20 per cent sodium hydroxide for some time. After washing with water the ethereal solution was dried with sodium sulfate, the ether evaporated, and the oily residue distilled in vacuum. At 1 mm. pressure the oil went over at the same temperature as before; *viz.*, at 102° . It weighed 2.5 gm. It had the same appearance, odor, and properties as before treatment with sodium hydroxide. On analysis it gave the following results.

0.1608 gm. of substance gave 0.1599 gm. H_2O and 0.4652 gm. CO_2 .
Found: C = 78.90; H = 11.12 per cent.

The composition agrees fairly well with the formula $C_{10}H_{14}O$.

For $C_{10}H_{14}O = 152$. Calculated: C = 78.94; H = 10.52 per cent.

Attempts to Prepare Crystalline Derivatives from the Oil $C_{10}H_{14}O$.

The substance did not react with phenylisocyanate and consequently it cannot contain an $-OH$ group. It gave no crystalline derivatives with phenylhydrazine hydrochloride and it did not react with sodium bisulfite.

A crystalline semicarbazone, however, was obtained as follows. 0.76 gm. of the oil was dissolved in 10 cc. of glacial acetic acid and to it were added 0.6 gm. of semicarbazide hydrochloride and 0.8 gm. of sodium acetate dissolved in 2 cc. of water. The solution was allowed to stand for 2 days at room temperature. It was then diluted with water and the oil which separated was extracted with ether. The ethereal solution was shaken with dilute sodium hydroxide to remove acetic acid and then dried over sodium sulfate. After evaporating the ether, the oily residue was trans-

ferred to a crystallizing dish with ether and the latter evaporated in a vacuum desiccator. The oil which remained crystallized nearly completely on standing. The crystals were freed from adhering oil as much as possible by pressing between filter paper and then recrystallized from benzene from which it separated in plates. It was again recrystallized by dissolving in a little methyl alcohol and adding hot water until the solution turned cloudy. On cooling, the substance separated in colorless plates. After standing in the ice box over night the crystals were filtered off, washed in 50 per cent methyl alcohol and water, and then dried at 100° . The product was snow-white and was practically odorless, and it weighed about 0.1 gm. When slowly heated it melted at 165° (uncorrected). It was analyzed after drying at 105° in vacuum over phosphorus pentoxide, when it did not lose in weight.

0.0798 gm. of substance gave 0.0692 gm. H_2O and 0.1838 gm. CO_2 .

For $\text{C}_{10}\text{H}_{16}$: N. $\text{NH}_4\text{CO}_2\text{NH}_2 = 209$.

Calculated: C = 63.15; H = 9.09; N = 20.09 per cent.

Found: C = 62.82; H = 9.70 per cent.

Unfortunately we were unable to make any further tests to determine the nature or constitution of this neutral oil on account of lack of material, most of the substance having been used up in making preliminary experiments. There appears, however, to be no doubt that the neutral non-phenolic oil obtained from cow urine during the summer has the composition $\text{C}_{10}\text{H}_{16}\text{O}$ and is isomeric with camphor.

Further Preparation of the Non-Phenolic Volatile Oil from Cow Urine.

About 430 liters of mixed urine from a herd of cows were collected during the winter, from February 29 to March 25. The fresh urine was evaporated and distilled as before. The distillates were extracted with ether. The ethereal solutions were vigorously shaken with three separate portions of 20 per cent sodium hydroxide and then with dilute sulfuric acid and finally washed with water. After drying with sodium sulfate the ether was evaporated and the oily residue distilled in vacuum. There were obtained 8.2 gm. of a light yellow oil of a penetrating, not unpleasant odor. The aqueous solution gave no reaction with

ferric chloride, but it reacted slightly with concentrated nitric acid which indicated the presence of phenols. For further purification the oil was transferred to a distilling flask with a little ether and vigorously shaken with 20 per cent sodium hydroxide and finally distilled with steam.

The light yellow oil which went over was extracted with ether, dried with sodium sulfate, and after filtering and evaporating the ether the residue was fractionated.

The alkaline liquid above, remaining after distilling with steam, was extracted with ether and then acidified with sulfuric acid. The oily substance which separated was taken up with ether, the latter dried and evaporated, and the residue distilled. The oil went over at about 76° and 2 mm. pressure. It weighed 2.7 gm. It was a practically colorless oil of distinct phenolic odor. With concentrated nitric acid it reacted with great violence. It was completely soluble in concentrated alkali. The aqueous suspension gave a fine blue coloration with ferric chloride. When cooled in a freezing mixture of ice and salt the oil crystallized to a white mass. All of these reactions indicate that the substance was cresol. It is evident from this how difficult it is to extract all of the phenols or cresols from an ethereal solution even with 20 per cent sodium hydroxide.

The volatile oil mentioned above after distilling over sodium hydroxide was further fractionated, and yielded two principal fractions. Fraction 1 showed the same boiling point as the cresol and weighed 1 gm. It was a light yellow oil of pleasant ethereal and non-phenolic odor. It gave no reaction with ferric chloride and did not react with concentrated nitric acid. It was insoluble in concentrated alkali. Neither nitrogen nor sulfur could be detected. It gave the following results on analysis.

0.1285 gm. of substance gave 0.1219 gm. H_2O and 0.3523 gm. CO_2 .

Found: C = 74.77; H = 10.61 per cent.

This nearly agrees with tetrahydrocresol $C_7H_{10}O = 112$.

Calculated: C = 75.00; H = 10.71 per cent.

An attempt was made to prepare a derivative with phenylisocyanate as follows: 0.56 gm. of the oil was mixed with 0.60 gm. of phenylisocyanate in a dry test-tube which was immediately sealed. It was gently warmed for a short time and allowed to

stand at room temperature over night. A considerable amount of colorless crystals had then separated. In the hope of completing the crystallization the tube was heated on the water bath for several hours. All the crystals had then dissolved and it was found impossible to induce the formation of any further crystallization in the solution; even on standing for several weeks not a single crystal formed. The small available quantity of the oil prevented any further examination.

Fraction 2 of the above neutral oil went over at about 100° at 0.25 mm. pressure. This portion weighed 2.5 gm. and as far as color, odor, and reactions were concerned it seemed to be identical with the non-phenolic oil $C_{10}H_{16}O$ previously described in this paper. It also had the same composition and it was free from nitrogen and sulfur.

0.1592 gm. of substance gave 0.1489 gm. H_2O and 0.4571 gm. CO_2 .

Found: C = 78.30; H = 10.46 per cent.

For $C_{10}H_{16}O$ = 152. Calculated: C = 78.94; H = 10.52 per cent.

Although the oil had the same percentage composition as the product isolated from cow urine during the summer it was different in that it did not give a crystalline semicarbazone. After acting upon the substance with semicarbazide hydrochloride in the same way as before an oil was obtained which did not crystallize and on distillation in high vacuum nearly one-half of the original oil was recovered unchanged as it boiled at the same temperature and it had the same composition.

Found: C = 79.15; H = 10.49 per cent.

A considerable residue remained in the distillation flask. It was a sticky, non-crystallizable syrup which contained a large quantity of nitrogen. It was probably a condensation product with semicarbazide but it did not crystallize itself nor could it be brought to crystallization in any of the usual solvents.

It would seem, then, that a portion of the non-phenolic oil excreted during the winter, although it has the same percentage composition, differs in constitution from the oil excreted during the summer. In addition, the winter urine contained an oil having a lower boiling point and a lower carbon content than that obtained in the summer.

We believe for this reason that the nature of the terpene-like substances contained in the feed condition the nature and composition of the volatile oils excreted in the urine. If this view is correct it is not surprising that the non-phenolic volatile oils excreted in the urine during the winter differ from those which are excreted in the summer when a part of the ration consists of green grass. It also follows that the non-phenolic oils of the urine are not constant metabolic products but that their nature to a large extent will depend upon the nature of the mother substances contained in the feed and are consequently of minor importance in the animal metabolism.

SUMMARY.

It has been shown that the so called neutral oil obtained from cow urine consists for the greater part of *p*-cresol. Mixed with this, however, there is *present a very small percentage of an aromatic non-phenolic oil of agreeable odor having the composition $C_{10}H_{16}O$* . This substance is present in larger amount during the summer than in the winter. The non-phenolic oils excreted during the winter are not chemically identical with those eliminated during the summer. The nature of these substances apparently depends upon the nature of the terpene-like bodies contained in the feed which the animals obtain.

The substance called "Urogon" by Mooser is a mixture of *p*-cresol and the above non-phenolic neutral oils.

The "Urogol" of Mooser we have shown to give the same derivatives as *p*-cresol and hence we believe that "Urogol" and *p*-cresol are identical.

Attention is called to the difficulty of removing phenols from an ethereal solution of phenols and non-phenolic oils by extraction with aqueous alkali.

CONCERNING CERTAIN AROMATIC CONSTITUENTS OF URINE.

II. THE NON-PHENOLIC VOLATILE OILS OF GOAT URINE.

By R. J. ANDERSON.

(From the Chemical Laboratory of the New York Agricultural Experiment Station, Geneva.)

(Received for publication, July 24, 1916.)

INTRODUCTION.

It has been shown in a previous report from this laboratory¹ that the neutral oil, the so called "Urogon" of Mooser,² isolated from the distillates of acidified cow urine consists principally of *p*-cresol mixed with a very small percentage of a non-phenolic volatile oil having the composition represented by the formula $C_{10}H_{16}O$, thus confirming the opinion expressed by Neuberg and Czapski³ that "Urogon" was not a homogeneous substance but a mixture consisting largely of *p*-cresol. Since it has been claimed by Fricke⁴ that the distillates from goat urine yield a neutral oil identical with "Urogon," we have also prepared and examined the neutral oil obtained from this source.

The goat urine was concentrated and distilled in the same way as the cow urine and the oil was isolated in the same manner. By treatment with 20 per cent sodium hydroxide this neutral oil or "Urogon" was separated into two portions—the alkali-soluble and the alkali-insoluble.

The alkali-soluble portion was found to be identical in every respect with *p*-cresol. It combined with phenylisocyanate giving a crystalline compound which had the composition and melting point required for *p*-cresol urethane, and by the action of nitric acid the 3-5-dinitro *p*-cresol was also formed. These

II. THE NON-PHENOLIC VOLATILE OILS OF GOAT URINE.

By R. J. ANDERSON.

(From the Chemical Laboratory of the New York Agricultural Experiment
Station, Geneva.)

(Received for publication, July 24, 1916.)

INTRODUCTION.

It has been shown in a previous report from this laboratory¹ that the neutral oil, the so called "Urogon" of Mooser,² isolated from the distillates of acidified cow urine consists principally of *p*-cresol mixed with a very small percentage of a non-phenolic volatile oil having the composition represented by the formula $C_{10}H_{16}O$, thus confirming the opinion expressed by Neuberg and Czapski³ that "Urogon" was not a homogeneous substance but a mixture consisting largely of *p*-cresol. Since it has been claimed by Fricke⁴ that the distillates from goat urine yield a neutral oil identical with "Urogon," we have also prepared and examined the neutral oil obtained from this source.

The goat urine was concentrated and distilled in the same way as the cow urine and the oil was isolated in the same manner. By treatment with 20 per cent sodium hydroxide this neutral oil or "Urogon" was separated into two portions—the alkali-soluble and the alkali-insoluble.

The alkali-soluble portion was found to be identical in every respect with *p*-cresol. It combined with phenylisocyanate giving a crystalline compound which had the composition and melting point required for *p*-cresol urethane, and by the action of nitric acid the 3-5-dinitro *p*-cresol was also formed. These

¹ Anderson, R. J., *J. Biol. Chem.*, 1916, xxvi, 387.

² Mooser, W., *Z. physiol. Chem.*, 1909, lxiii, 155.

³ Neuberg, C., and Czapski, L., *Biochem. Z.*, 1914, lxxvii, 28.

⁴ Fricke, E., *Arch. ges. Physiol.*, 1914, clvi, 225.

derivatives in addition to the reactions and properties of the substance itself leave no doubt that it was *p*-cresol.

The alkali-insoluble portion of the crude neutral oil was found to be identical in every particular with the non-phenolic oil isolated from cow urine. It had the same appearance and odor and in composition it agreed with the formula $C_{10}H_{16}O$. This oil gave a crystalline semicarbazone when acted upon with semicarbazide hydrochloride in glacial acetic acid solution which in crystal form and solubilities was identical with the semicarbazone obtained from the oil from cow urine and like the latter it melted at 165° .

It is evident, therefore, that the neutral oils or "Urogon" isolated from cow and goat urine are identical and that they consist of a mixture containing principally *p*-cresol with a small percentage of a non-phenolic volatile oil having the composition expressed by the formula $C_{10}H_{16}O$.

EXPERIMENTAL.

The urine was collected during the summer when the animals were fed on green alfalfa, hay, oats, and corn meal. After evaporating the fresh urine to about one-eighth of its volume it was strongly acidified with sulfuric acid and distilled, partly direct and partly with steam, until no further oil appeared in the distillate. The distillates were transferred to a large separating funnel and rendered strongly alkaline with sodium hydroxide and then extracted several times with ether. The ethereal solutions were again shaken with sodium hydroxide and then with dilute sulfuric acid and finally washed several times with water. After drying with sodium sulfate and filtering, the ether was evaporated. The oily residue was of dark yellow color and it possessed a very penetrating, persistent, and disgusting odor which resembled the natural odor peculiar to goats. In all, 45 liters of goat urine were distilled which yielded 22.3 gm. of oil after distilling in vacuum at 1 mm. pressure.

The distillate was a light yellow oil of the same disgusting odor as the raw product. It was neutral to litmus and contained neither nitrogen nor sulfur. With concentrated nitric acid it reacted with great violence. Suspended in water it was immedi-

ately oxidized by potassium permanganate. It did not reduce Fehling's solution but an alkaline solution of silver nitrate was reduced on heating. In chloroform solution the substance takes up bromine with liberation of hydrobromic acid. The oil is easily soluble in all proportions in the ordinary organic solvents but insoluble in water or dilute alkali. When treated with concentrated alkali the disgusting odor disappeared and a pleasant terpene-like odor resulted. On analysis the following result was obtained.

0.1537 gm. of substance gave 0.1078 gm. H_2O and 0.4350 gm. CO_2 .
Found: C = 77.19; H = 7.84 per cent.

These figures agree with those found for the neutral oil from cow urine.¹ The composition is also identical with that of the substance called "Urogon" by Mooser.²

Since the oil had been extracted from a strongly alkaline liquid and as the ethereal solution had been further treated with sodium hydroxide it was thought that phenols had been completely removed. However, this was by no means the case, as will be shown below.

The oil was further carefully fractionated in high vacuum at about 1 mm. pressure when the temperature rose slowly but continuously, indicating that the substance was not homogeneous. After the greater portion had been distilled, the residue, a light yellow oil, was taken up in a little ether and shaken for a long time with 20 per cent sodium hydroxide. The ethereal solution was washed with water, dried with sodium sulfate, filtered, and the ether evaporated.

The oily residue was distilled and at 1 mm. pressure it went over between 101–102°. The distillate, which weighed 1.5 gm., was a light yellow colored oil, of agreeable terpene-like odor and it appeared identical with the oil obtained from cow urine. It dissolved in concentrated sulfuric acid with a red color. It gave no reaction with concentrated nitric acid; on warming the acid the oil dissolved without any visible reaction and on diluting with water a cloudy solution resulted. It was insoluble in 20 per cent sodium hydroxide or in 40 per cent potassium hydroxide and on heating these solutions to boiling the oil turned brown in color. It did not crystallize or solidify on cooling in a freezing

mixture to -20° . The aqueous suspension gave no color reaction with ferric chloride. Alkaline silver nitrate was reduced on heating and potassium permanganate was decolorized at room temperature.

The first and principal portion of the distillate mentioned above was treated with sodium hydroxide, 20 per cent, in the same manner and it yielded 0.9 gm. of the non-phenolic oil boiling at $101-102^{\circ}$ at 1 mm. pressure.

The alkaline solutions were reserved for further examination. The non-phenolic oils were analyzed and the following result was obtained.

First Preparation.

0.1716 gm. of substance gave 0.1713 gm. H_2O and 0.4923 gm. CO_2 .
Found: C = 78.24; H = 11.17 per cent.

Second Preparation.

0.1008 gm. of substance gave 0.1019 gm. H_2O and 0.2908 gm. CO_2 .
Found: C = 78.68; H = 11.31 per cent.
For $C_{10}H_{10}O = 152$. Calculated: C = 78.94; 10.52 per cent.

Preparation of the Semicarbazone.

The oil, 1.1 gm., was dissolved in 13 cc. of glacial acetic acid and to it was added a solution of 0.9 gm. semicarbazide hydrochloride and 1.3 gm. of sodium acetate in 2.5 cc. of water. After standing for 3 or 4 days at room temperature, the perfectly clear solution was diluted with water and the oily substance which separated was extracted with ether. The ethereal solution was washed with dilute sodium hydroxide to remove acetic acid and then washed with water and dried with sodium sulfate. After filtering, the ether was evaporated. The oily residue crystallized partially on standing. To remove adhering oil the substance was spread upon a clay plate. The pure white crystalline substance which remained was twice recrystallized by dissolving in hot methyl alcohol and adding hot water until the solution turned cloudy. On cooling, the substance separated in colorless plates. The snow white product finally obtained weighed 0.1 gm. The crystal form was identical with that of the semicarbazone obtained from the non-phenolic oil from cow urine and like the

latter this substance also melted sharply at 165° (uncorrected). Since the crystal form and melting point of the two semicarbazones were exactly alike we believe that the substances were identical.

Examination of the Alkali-Soluble Portion of the Crude Neutral Oil.

The alkaline solution was acidified with sulfuric acid and the oil which separated was extracted with ether. The ethereal solution was dried with sodium sulfate, filtered, and the ether distilled off. The oil which remained was distilled in vacuum and at about 1 mm. pressure it went over at 76° . It was obtained as a practically colorless oil of distinctly phenolic odor. It was completely soluble in 20 per cent sodium hydroxide. It reacted with great violence with a concentrated nitric acid. In concentrated sulfuric acid it dissolved with a faint red color. When cooled in a freezing mixture of ice and salt it crystallized to a white solid mass which again liquefied at room temperature. Its aqueous solution or suspension gave a fine blue color with ferric chloride. At atmospheric pressure the oil boiled at 198° (uncorrected). The analysis gave the following result.

0.1042 gm. of substance gave 0.0744 gm. H_2O and 0.2949 gm. CO_2
0.1696 gm. of substance gave 0.1172 gm. H_2O and 0.4816 gm. CO_2 .
Found: C = 77.18; H = 7.99 per cent.
C = 77.44; H = 7.55 per cent.
For cresol, $\text{C}_7\text{H}_8\text{O}$ = 108. Calculated: C = 77.77; H = 7.40 per cent.

Preparation of Cresol Urethane.

The cresol urethane was easily prepared according to the method of Snape⁵ as follows: 1.08 gm. of the substance analyzed above and 1.19 gm. of phenylisocyanate were heated in a sealed tube for 16 hours in the steam bath. At the end of this time the content was still fluid but on shaking for a few minutes it crystallized, forming a solid mass. The substance was removed from the tube and washed several times with petroleum ether. It was then recrystallized by dissolving in 20 cc. of hot alcohol and adding hot water until the solution turned cloudy. On scratching, the substance began to separate in large colorless plates. After

⁵ Snape, H. L., *Ber. chem. Ges.*, 1885, xviii, 2429.

standing in ice water for some time the crystals were filtered off and washed in dilute alcohol. The substance was again recrystallized from 10 cc. of hot alcohol from which it separated, on cooling slowly, in long colorless needles or prisms. When the alcoholic solution is cooled quickly the substance separated in large colorless plates. The crystals were filtered and washed in a little ice cold alcohol and allowed to dry in the air. Yield: 0.9 gm. The balance of the substance can be obtained by adding water to the alcoholic solution.

When heated in a capillary tube the substance melted at 113° (uncorrected). According to Leuckart,⁶ as quoted in Beilstein, the urethane of *p*-cresol melts at 114° . After drying at 100° in vacuum over phosphorus pentoxide when it did not lose in weight the substance was analyzed.

0.1391 gm. of substance gave 0.0720 gm. H_2O and 0.3760 gm. CO_2 .

For cresol urethane $CH_3.C_6H_4O.CO.NH.C_6H_5 = 227$.

Calculated: C = 74.01; H = 5.72; N = 6.16 per cent.

Found: C = 73.72; H = 5.79 per cent.

Preparation of the Dinitro Cresol.

The oil itself, as has been mentioned previously, reacts with great violence with concentrated nitric acid. Sometimes long yellow needles separate when the reaction mixture cools but most frequently dark colored oily masses are obtained. However, the dinitro derivative is easily obtained by the method mentioned in Beilstein. About 4 gm. of the oil were dissolved in 4 cc. of glacial acetic acid. To this solution was added slowly a mixture of 6 cc. of concentrated nitric acid dissolved in 6 cc. of glacial acetic acid. The vigorous reaction was soon completed and on standing a short time the nitro compound began to separate in long needles. After standing for 2 hours in the ice box the yellow crystals were filtered off and washed thoroughly in water. For recrystallization the substance was dissolved in a large quantity of boiling water (about 1.5 liters). The substance is very slightly soluble in water. At first it melts in the hot water and dissolves very slowly on continued boiling. After filtering and cooling slowly to room temperature long delicate golden yellow needles

⁶ Leuckart, R., *J. prakt. Chem.*, 1890, xli, 319.

separated. These were filtered off, washed in water, and dried over sulfuric acid in a vacuum desiccator.

The crystals melted when heated in a capillary tube at 83° (uncorrected). The 3-5-dinitro *p*-cresol according to Beilstein melts at 85° . The substance does not contain any water of crystallization as it does not lose in weight on drying over phosphorus pentoxide at the temperature of boiling chloroform. From alcohol the substance crystallizes in very massive dark yellow needles which also melted at 83° . On analysis the following result was obtained.

0.1718 gm. of substance gave 0.0509 gm. H_2O and 0.2678 gm. CO_2 .

For dinitro cresol, $\text{CH}_3 \cdot \text{C}_6\text{H}_2(\text{NO}_2)_2 \cdot \text{OH} = 198$.

Calculated: C = 42.42; H = 3.03; N = 14.14 per cent.

Found: C = 42.51; H = 3.31 per cent.

For comparison with the above dinitro cresol we prepared a dinitro compound by the same method from the cresol isolated from cow urine. From the distillates from cow urine we had obtained about 300 gm. of cresol as a by-product in the preparation of the non-phenolic volatile oils previously described.¹ The two dinitro derivatives were found to be identical in every respect. The dinitro cresol from cow urine crystallized from alcohol in massive dark yellow needles which melted at 83° (uncorrected), and from water it separated in long delicate golden yellow needles which also melted at 83° (uncorrected). The identity of the two substances was further confirmed by the analysis.

0.1177 gm. of substance gave 0.0339 gm. H_2O and 0.1817 gm. CO_2 .

Found: C = 42.10; H = 3.22 per cent.

There appears to be no doubt from the work reported above that the alkali-soluble portion of the crude oil obtained from goat urine was identical with the oil obtained under similar conditions from cow urine. The study of the substance itself and the derivatives mentioned above makes it evident that the oil is *p*-cresol. The substance is also identical with the phenol called "Urogol" by Mooser.² Since we have shown, however, that the above oil is identical with *p*-cresol it is evident that "Urogol" also is not isomeric but identical with *p*-cresol.

SUMMARY.

The experimental data presented in this paper show that the neutral oil obtained from goat urine, which was described under the name of "Urogon" by Fricke, is a mixture.

The oil contains principally *p*-cresol mixed with a small percentage of a non-phenolic volatile oil, the composition corresponding to the formula $C_{10}H_{16}O$.

Both of these substances are identical with the oils isolated from cow urine.

CONCERNING CERTAIN AROMATIC CONSTITUENTS OF URINE.

III. THE NON-PHENOLIC VOLATILE OILS OF HORSE AND HUMAN URINE.

By R. J. ANDERSON.

(From the Chemical Laboratory of the New York Agricultural Experiment
Station, Geneva.)

(Received for publication, July 24, 1916.)

INTRODUCTION.

It was reported by Städeler¹ that the distillates from acidified urines from horses and human beings contained certain alkali-insoluble volatile oils similar to the oil obtained from cow urine. Other investigators have observed and confirmed this report of Städeler. Hoppe-Seyler² states that in horse urine there occur in addition to phenols also volatile camphor-like substances and Baumann,³ in his exhaustive investigations concerning the conjugated sulfuric acids in urine observed a similar substance. This author states, "Destilliert man das durch Zersetzung einer grösseren Menge Pferdeharn erhaltene, auf dem Wasser meist schwimmende Oel mit Ätzkali, so erhält man im Destillat auf dem Wasser schwimmende gelbe oelige Tropfen die frei von phenolartige Körper sind. Dieselben besitzen einen eigentümlichen, an gewisse ätherische Oele erinnernden Geruch." Brieger⁴ describes a similar oil obtained from human urine. This substance is described as a light yellow colored oil of pleasant peppermint-like odor. By cooling, it neither solidified nor crystallized. It contained nitrogen. It gave red colorations with fuming nitric acid, concentrated sulfuric acid, and with Millon's reagent. With concentrated hydrochloric acid it gave a fine red color which changed into blue and after a while into a dirty violet. Bromine water gave a resinous precipitate but the oil gave no color reaction with ferric chloride. Given to a rabbit it caused no visible disturbance.

³ Baumann, E., *Arch. ges. Physiol.*, 1876, xiii, 285.

⁴ Brieger, L., *Z. physiol. Chem.*, 1880, iv, 204.

It has been claimed by Fricke⁵ that both horse and human urine contain the substance "Urogon" described by Mooser⁶ as existing in cow urine. We⁷ have shown, however, that the substance "Urogon" is not homogeneous but a mixture consisting of *p*-cresol and a non-phenolic oil having the composition $C_{10}H_{16}O$, our results confirming the opinion expressed by Neuberg and Czapski.⁸

Dehn and Hartman⁹ have recently reported the discovery in human urine of a substance which they call "Urinod." This substance is supposed to be the cause of the characteristic odor of urine and it is described as possessing other remarkable properties. It reacted with concentrated nitric acid with explosive violence and when treated with fixed alkalis a terpene-like odor was produced. The substance combined with bromine with liberation of hydrobromic acid. It gave no definite compounds with semicarbazide or hydroxylamine hydrochlorides but a crystalline dinitro derivative was obtained.

In the present investigation we have confined ourselves entirely to the non-phenolic or alkali-insoluble portion of the oils obtained on distilling acidified horse urine and human urine. In the preparation of the so called neutral or alkali-insoluble oils from the distillates of urine it is necessary to bear in mind that the distillates contain large quantities of phenols principally *p*-cresol and a very small percentage of really neutral or alkali-insoluble oils. We have previously referred to the difficulty of completely removing phenols from an ethereal solution by shaking the latter with aqueous alkali⁷ and Neuberg and Czapski⁸ have shown that both phenol and cresol may be extracted by petroleum ether from a strongly alkaline solution. Various authors like Mooser⁶ Fricke,⁵ and Dehn and Hartman⁹ apparently have not taken the importance of this matter into account and have failed to assure themselves that phenols and cresols had been completely removed from the so called neutral oils which they finally obtained and analyzed.

We cannot believe that the oil described under the name of "Urinod" by Dehn and Hartman⁹ is any more of a chemically homogeneous substance than the "Urogon" of Mooser and Fricke.

⁵ Fricke, E., *Arch. ges. Physiol.*, 1914, clvi, 225.

⁸ Neuberg, C., and Czapski, L., *Biochem. Z.*, 1914, lxxvii, 28.

⁹ Dehn, W. M., and Hartman, F. A., *J. Am. Chem. Soc.*, 1914, xxxvi,

The properties ascribed to "Urinod" are practically identical with those which we have observed in the case of all so called neutral oils obtained from cow and goat urines. The peculiar chemical reactivity of these oils, *viz.*, the violent reaction with concentrated nitric acid and the absorption of bromine with liberation of hydrobromic acid, is due to the cresol contained in such oils and we feel quite certain that the substance called "Urinod" must also have been largely contaminated with phenol or cresol since it would have been practically impossible, in accordance with our experience, completely to remove all of the phenols by the method employed by Dehn and Hartman.

The peculiar and disgusting odors possessed by all of the crude neutral oils obtained from urine distillates are apparently caused by very minute quantities of powerfully odorous substances. These odors, moreover, differ according to the kind of urine from which the oils are isolated. The oil from goat urine, for instance, has a powerful and disgusting odor of goats, that from cow urine smells like the odor peculiar to cow stables, and the oil from human urine has a strong and persistent odor which is very similar to that of human urine. These odors are destroyed by nitric acid, as stated by Dehn and Hartman, and they are also immediately destroyed by concentrated alkali when brought into direct contact with the crude oils. We have noticed also that these odors are lost on repeated fractionation of the oils in high vacuum. For this reason we believe that these highly odorous substances are very volatile bodies which are merely dissolved in the crude oils. The crude oils like "Urogon" and "Urinod" contain therefore not less than three substances; *viz.*, (1) principally cresol; (2) a small percentage of alkali-insoluble neutral oils which vary according to the terpene-like bodies contained in the food; and (3) the disgusting odorous bodies.

The first two can be separated by means of sufficiently concentrated alkali which dissolves out the cresol leaving the alkali-insoluble oil but the odorous substances become destroyed by this treatment, because the residual insoluble oil possesses an agreeable terpene-like odor and the cresol isolated after acidifying the alkaline solution has a pure phenolic odor without any trace of the disgusting odor of the original substance.

It would be interesting to study further these odorous sub-

stances. Such studies, however, are very difficult because these substances are apparently present in exceedingly minute quantities. Although we have tried to obtain some knowledge concerning their nature we have been unable to secure any other evidence of their existence than the smell.

EXPERIMENTAL.

The Non-Phenolic Volatile Oil from Horse Urine.

About 67 liters of mixed horse urine were collected during the winter. The fresh urine was evaporated to about one-eighth of its volume, strongly acidified with sulfuric acid, and distilled with steam until no more oil went over. The distillates were extracted with ether and the ethereal solution was repeatedly shaken with 20 per cent sodium hydroxide and then with dilute sulfuric acid, finally washed with water, and dried with sodium sulfate. After evaporating the ether the oily residue was distilled in vacuum. There were obtained 2 gm. of a light yellow oil which in odor resembled the product previously isolated from cow urine, but it differed in composition by containing nearly 3 per cent more hydrogen.

0.1353 gm. of substance gave 0.1251 gm. H_2O and 0.3831 gm. CO_2 .
Found: C = 77.22; H = 10.35 per cent.

The substance reacted slightly with concentrated nitric acid which indicated traces of cresol.

The oil was, therefore, thoroughly shaken with 20 per cent sodium hydroxide until a milky emulsion was formed. This was extracted with ether and after drying and evaporating the ether the residue was again distilled in vacuum. At about 1 mm. pressure it went over at 100° . It was a light yellow colored oil of pleasant aromatic or terpene-like odor which weighed 0.7 gm. It was free from nitrogen and sulfur.

The alkaline solution, after extracting the above alkali-insoluble oil, was acidified with sulfuric acid, the oily substance was extracted with ether, and finally distilled in vacuum. The distillate went over at 76° and 2 mm. pressure. It was a practically colorless oil of distinct phenolic odor which when suspended in water

gave a fine blue coloration with ferric chloride and it reacted with great violence with concentrated nitric acid. There appears to be no doubt, therefore, that this substance was cresol.

This shows again how difficult it is to extract all of the phenols from an ethereal solution by aqueous alkali. Traces of cresol remained in this oil in spite of the fact that the ethereal solution had repeatedly been shaken thoroughly with 20 per cent sodium hydroxide.

Properties of the Above Alkali-Insoluble or Neutral Oil.

The aqueous suspension of the oil gives no color reaction with ferric chloride. It does not solidify in a freezing mixture of ice and salt. When mixed with cold concentrated nitric acid the oily globules assume a red color and on warming, the oil dissolves, giving a yellow solution which on dilution with water turns cloudy. With cold concentrated hydrochloric acid no change takes place but on heating the oil turns red in color. In cold concentrated sulfuric acid the oil dissolves giving a dark red solution. In chloroform solution bromine is absorbed with liberation of hydrobromic acid. Potassium permanganate solution is immediately decolorized. Ammoniacal silver nitrate is reduced on heating. It is soluble in all proportions in the ordinary organic solvents but insoluble in alkali or water. On analysis the following result was obtained.

0.1247 gm. of substance gave 0.1224 gm. H_2O and 0.3423 gm. CO_2 .

Found: C = 74.86; H = 10.98 per cent.

The percentage composition agrees with the formula $\text{C}_7\text{H}_{12}\text{O}$.

Calculated for this: C = 75.00; H = 10.71 per cent.

The Non-Phenolic Oil from Human Urine.

The fresh urine which was acid in reaction was made slightly alkaline by adding sodium carbonate and then evaporated to about one-eighth of its volume. The residue was acidified with sulfuric acid, distilled with steam, the distillate extracted with ether, and the ethereal solution shaken repeatedly with 20 per cent sodium hydroxide and then with dilute sulfuric acid. In

all 111 liters of urine were evaporated and distilled. A small amount of yellow colored oil remained on evaporating the ether. The oil possessed a strong and persistent odor of human urine and it reacted slightly with concentrated nitric acid. In order to remove phenols completely the oil was shaken for some time with 20 per cent sodium hydroxide and distilled from the alkaline solution with steam. The distillate was extracted with ether, the latter dried with sodium sulfate, filtered and evaporated, and the residue distilled in vacuum when about 0.15 gm. of a light yellow oil was obtained. It did not contain nitrogen.

This oil had an agreeable terpene-like odor, the odor of urine of the original crude oil having been lost in the treatment with sodium hydroxide. In other respects it gave exactly the same reactions as described for the oil isolated from horse urine and it had practically the same composition.

0.1005 gm. of substance gave 0.0909 gm. H_2O and 0.2777 gm. CO_2 .
Found: C = 75.36; H = 10.12 per cent.

This substance differs in composition from the "Urinod" of Dehn and Hartman⁹ by containing about 2 per cent more hydrogen. It also differs from the above product by giving no reaction with concentrated nitric acid. The violent reaction produced when "Urinod" was treated with concentrated nitric acid was undoubtedly due to the presence of phenols.

Unfortunately the quantity of neutral oil obtained from horse urine and from human urine was too small to permit of a more extensive investigation. Of all the urines examined that from human beings contained the smallest percentage of neutral oil. Städeler¹ also reported that the amount of oil obtained from human urine was very slight.

As a result of our investigation of the neutral alkali-insoluble oils obtainable from the urine of different animals we have found only two different kinds of oil as far as composition is concerned, as is shown in the résumé below.

Composition:			Corresponding to the formula:
	C	H	
Cow urine.....	78.25	10.84	$C_{10}H_{16}O$
	78.90	11.12	Calculated: C = 78.94; H = 10.52
	78.30	10.46	
	79.15	10.49	
Goat urine.....	78.24	11.17	
	78.63	11.31	
Cow urine.....	74.77	10.61	Corresponding to the formula:
Horse urine.....	74.86	10.98	$C_7H_{12}O$
Human urine.....	75.36	10.12	Calculated: C = 75.00; H = 10.71.

In conclusion we venture to express the opinion that the kind of neutral alkali-insoluble oils excreted in the urine of different animals will be found to a large extent to depend upon the nature of the terpene-like bodies contained in the food and for this reason the nature of the oil will vary in accordance with the season and the available food supply.

THE LIPOIDS ("FAT") OF THE BLOOD IN DIABETES.

By W. R. BLOOR.

WITH THE COOPERATION OF E. P. JOSLIN AND A. A. HORNOR.

(From the Laboratories of Biological Chemistry of the Harvard Medical School,
Boston.)

(Received for publication, July 21, 1916.)

Diabetes has been almost universally regarded as primarily a disturbance of the carbohydrate metabolism. The abnormalities in fat metabolism which accompany it and sometimes precede the characteristic symptom—the glycosuria—are accepted by most as being secondary to the disorder of the carbohydrate metabolism. Thus the acidosis produced by the unburned residues of the fatty acids is explained as the result of the lack of available carbohydrates—"the fats can burn only in the fire of the carbohydrates." The obesity which precedes the glycosuria in a considerable proportion of the cases (15 to 45 per cent),¹ is explained as the result of fat formation from carbohydrate which the organism can no longer burn. There are, however, some dissenters who claim a "lipogenetic" origin of diabetes,² basing their claim on the frequent occurrence of obesity preceding diabetes and the occasional clinical observation that the rapid laying on of fat is accompanied by glycosuria which disappears when the fattening process is stopped. But whatever opinion may be held regarding the origin of diabetes all are agreed that in severe diabetes the ability of the organism to utilize fat may be markedly affected. The earliest observation definitely connecting a disordered fat metabolism with diabetes was that of lipemia—milkeness of the blood and particularly the serum, made at the time when bleeding was a common practice. Severe diabetes was practically the only disease in which lipemia was common enough to be regarded as of diagnostic significance. The milky appearance of the serum and the "cream" which

¹ Von Noorden, C., *Die Zuckerkrankheit und ihre Behandlung*, Berlin, 5th edition, 1910.

² Kisch, E. H., *Münch. med. Woch.*, 1911, lviii, 677.

arose from it on standing indicated that the substance producing the cloudiness was "fat," which was confirmed by extraction and examination. When the practice of bleeding fell into disuse nothing more was learned regarding the nature of this "fat" until nearly a hundred years later when Fischer³ found that the quantity of cholesterol in diabetic blood was abnormally high and a few years later Klemperer and Umber confirmed this finding and made the same observation with regard to "lecithin."⁴ In the considerable number of examinations made of the blood lipoids in diabetes during recent years there has been little uniformity in results.⁵ In some cases diabetic coma was found to be accompanied by a marked lipemia in which the increase in fat was accompanied by increases in "lecithin" and cholesterol; in others the lipemia was found to be due to fat alone. Again, coma and death have been reported without any marked change in the blood lipoids. The lack of concordance in results may be explained in part by the different and often inadequate methods of analysis employed. Also the nutritive condition of the patient was rarely taken into account, so that the lipemia may have been merely alimentary. Another fact which doubtless influenced the results was postmortem changes in the blood. The samples were taken in many cases after death, from the body cavities where the blood had stood for an indefinite time so that not only had degenerative changes taken place but also there was separation of the lipoids, and an accurate sample was not obtained. Even when the blood had been drawn from the living body it was allowed to stand for some time after removal (in one series of samples, 24 hours at body temperature).

Various explanations have been offered for the lipemia in diabetes. The occurrence of increased amounts of "lecithin" and cholesterol (cytolipoids) led to the belief that the increase was due to degeneration of tissue cells, setting free their lipoids, but analyses of various tissues⁶ have shown that the lipoid content of the tissues in diabetes is not abnormal. Increased mobilization of stored fat as the result of the partial starvation has also been offered as an explanation but here again the evidence does

³ Fischer, B., *Arch. path. Anat.*, 1903, clxxii, 30.

⁴ Klemperer, G., and Umber, H., *Z. klin. Med.*, 1907, lxi, 145.

⁵ Bloor, W. R., *J. Biol. Chem.*, 1916, xxv, 577.

⁶ Klemperer and Umber, *Z. klin. Med.*, 1908, lxxv, 340.

not bear out the assumption. In the first place the stored fat contains only traces of "lecithin" and cholesterol, and in the second place diabetics are generally thin and have very little stored fat; also even complete starvation does not necessarily mean increased blood fat.⁷ A third explanation was that the increase was due merely to accumulation of food fat which the organism was no longer able to burn, and in the light of the knowledge that in diabetes the fat-burning mechanism is probably deranged, and of the recent discovery that "lecithin" and probably cholesterol (as ester) are steps in normal fat metabolism,⁸ this seems to be the most reasonable explanation.

In view of the lack of definite information regarding the lipoids of the blood in as familiar a disease as diabetes a study of this phase of the subject seemed very desirable both from the point of view of a better understanding of the disease and a consequently more rational treatment, and also for obtaining an insight into fat metabolism in a condition which appears to be a natural experiment in this little known field.

For the investigation we were particularly fortunate in having available for study a group of patients in various stages of the disease all living in one house, under the care of a single physician and in charge of a single nurse who has had much experience in taking care of this class of patient. When it is added that we enjoyed throughout the intelligent cooperation of the patients themselves, it may be seen that the work was done with a control of conditions, dietary and otherwise, not often attained in investigations of this kind.⁹

The treatment given these patients has been reported recently⁹ and therefore need not be given here. It consisted essentially of fasting till sugar-free and then building up a tolerance for carbohydrate and protein. A notable feature in the treatment was that considerable attention was given to the fat of the diet. In severe, longstanding, and complicated cases the fast was not begun at once but only after the patients were given a preliminary treatment which consisted in first removing the fat from the

⁷ Bloor, *J. Biol. Chem.*, 1914, xix, 1.

⁸ The respiratory metabolism of nearly all these patients was being studied at the time the blood samples were taken and a full report of the results will appear in a publication of the Carnegie Institution.

⁹ Joslin, E. P., *Am. J. Med. Sc.*, 1915, cl, 485.

diet without otherwise changing conditions, then after 2 days omitting protein and halving the carbohydrate daily down to 10 gm. Fasting was then begun and carried out as usual. Fat was not added again to the diet until a considerable protein tolerance had been established. For reasons which will appear in the discussion, this modification of the fasting treatment is believed to be an important innovation.

The methods of analysis used were the same as those used in the earlier work on blood "fat" and need not be given in detail at this time.

In determining "lecithin" the strychnine molybdate precipitation was used with Kober's strychnine molybdate reagent.¹⁰ This precipitation has been found satisfactory. 15 cc. of the alcohol-ether blood extract were used for the determination in all but the severe diabetics where 10 cc. were sufficient. For the determination of cholesterol, 5 cc. of the extract were generally sufficient, although in the mild diabetics 10 cc. were required, in the severe ones 3 cc., and occasionally 1 cc. (lipemia) was the suitable amount. For "total fat" 10 cc. of the blood extract were generally used, although in some of the severe cases where the lipoids were high 5 cc. were used, and in the severe lipemia 1 cc. was used. The attempt was made throughout to use quantities of material in value not far from the standard so as to avoid making corrections. The blood samples were all taken before breakfast and were brought at once by special messenger to the laboratory where they were worked up promptly—in the great majority of cases within a half hour after drawing from the vein—thus avoiding postmortem changes.

The data regarding the patients which have a bearing on the reported results are as follows:

Men.

68 L-560.—Age 72 years, weight 154 pounds. Mild diabetic of 8 years' standing. Not fasted but diet cut down; at present getting 314 calories as carbohydrate 10 gm., protein 19 gm., fat 22 gm. Urine, sugar- and acid-free. Blood sugar 0.13 per cent.

71 S-998.—Age 72 years, weight 131 pounds. Mild. Diet, carbohydrate 15 gm., protein 20 gm., fat 0. Urine, sugar- and acid-free; blood sugar 0.21 per cent.

106 M-1026.—Age 22 years, weight 222 pounds. Duration 6 weeks.

¹⁰ Kober, P. A., and Egerer, G., *J. Am. Chem. Soc.*, 1915, xxxvii, 2373.

Mild diabètes. Very fat. Urine, sugar 0. diacetic acid reaction +. Blood sugar 0.20 per cent. Diet, carbohydrate 10 gm., protein 5 gm., fat 0; 60 calories.

107 Gr-1028.—Age 30 years, weight 123 pounds. Duration 1 year, mild. Urine, sugar- and acid-free. Blood sugar 0.25 per cent. Diet, carbohydrate 10 gm., protein 25 gm., fat 0, alcohol 15 gm.; 245 calories.

102 St-914.—Mild. Urine, sugar- and acid-free. Not under treatment or on a diet. Blood plasma somewhat cloudy (lipemia?).

80 P-1008.—Age 55 years, weight 113 pounds. Duration 14 years. Urine, sugar 5.4 per cent (102 gm.); diacetic acid 0. Blood sugar 0.35 per cent. Diet, carbohydrate 75 gm., protein 13 gm., fat 2 gm.; 370 calories.

74 Pa-632.—Age 33 years, weight 131 pounds. Duration 4 years. Onset acute on changing from active to sedentary life.

Sample I.—Urine, sugar- and acid-free. Blood sugar 0.24 per cent. Diet, carbohydrate 27 gm., protein 71 gm., fat 117 gm., alcohol 9 gm.; 1,508 calories.

Sample II. (98 Pa).—Urine, sugar- and acid-free. Blood sugar 0.17 per cent. Diet, carbohydrate 10 gm., protein 29 gm., fat 15 gm., alcohol 18 gm.; 417 calories.

Sample III. (105 Pa).—Urine, sugar- and acid-free; blood sugar 0.19 per cent. Fasting.

43T-966.—Age 39 years, weight 114 pounds. Duration 6 months.

Sample I.—Taken before the fasting period. Preliminary treatment, gradual reduction of carbohydrate. Diet, carbohydrate 13 gm., protein 3 gm., fat 0; 64 calories. Urine, sugar 1.2 per cent (27 gm.). Diacetic acid 4 +.

Sample II. (44T).—2nd day of fast. Urine, sugar 2 per cent. Diacetic acid reaction 3 +.

Sample III. (65T).—4 days after leaving hospital. Urine, sugar- and acid-free.

62 Tr-974.—Age 13 years, weight 70 pounds. Duration 6 weeks. 1st day of fasting. Sugar had appeared in the urine the day before but for 5 days previously had been sugar- and acid-free. On this day the urine was sugar- and acid-free. Blood sugar 0.19 per cent.

69D-821.—Age 25 years, weight 112 pounds. Duration 2 years. Urine, sugar 51 gm. Diacetic acid reaction 3 +. Diet, carbohydrate 20 gm., protein 5 gm., fat 0; 100 calories. Blood sugar day before 0.34 per cent.

63G-982.—Age 22 years, weight 141 pounds. Duration 2 years. Urine, sugar- and acid-free. Diet, carbohydrate 69 gm., protein 90 gm., fat 143 gm.; 1,923 calories.

110C-1029.—Age 37 years, weight 112 pounds. Duration 4 years. Urine, sugar- and acid-free. Blood sugar 0.26 per cent. Diet, carbohydrate 40 gm., protein 90 gm., fat 67 gm.; 1,123 calories.

51K-969.—Age 48 years, weight 115 pounds. Duration 6 years. Urine, sugar- and acid-free. Blood sugar 0.21 per cent. Diet, carbohydrate 22 gm., protein 56 gm., fat 96 gm.; 1,176 calories. During the preceding 2 weeks the carbohydrate tolerance had been built up from 0.

45Mc-951.—Age 33 years, weight 112 pounds. Duration 4 years. Urine,

sugar- and acid-free. Diet, carbohydrate 0, protein 55 gm., fat 62 gm., alcohol 9 gm.; 841 calories. On this diet for 2 weeks.

48 *Ca-810*.—Age 28 years, weight 92 pounds. Duration 14 months. Urine, sugar- and acid-free. Fasting between days of 666 and 728 calories.

42 *Cl-786*.—Age 40 years, weight 116 pounds. Duration 2½ years. Urine, sugar- and acid-free for the first time this day. Diet, carbohydrate 0, protein 28 gm., fat 16 gm.; 256 calories. On leaving the hospital this patient broke diet, eating, among other things, much cream, and returned to the hospital in a dangerous condition. His blood plasma, which under treatment had remained clear, was now like thick cream in appearance. The analysis of this blood is reported with the lipemias (124 *Cl*). At the time this last sample was taken he had fasted 14 hours and had had no fat for 36 hours.

Women.

47 *D-970*.—Age 59 years, weight 197 pounds. Duration 1½ months. Urine, sugar- and acid-free. Blood sugar 0.16 per cent. Fasted 1 day a week ago, since then building up carbohydrate tolerance. Diet, carbohydrate 25 gm., protein 60 gm., fat 27 gm.; 583 calories.

78 *A-1004*.—Age 45 years. Duration 5 months. Sample taken at beginning of coma. Died 2nd day after, in coma. Urine, sugar- and acid-positive. Blood sugar 0.41 per cent.

81 *T-1007*.—Age 56 years, weight 110 pounds. Duration 16 years. Blood sugar 0.13 per cent. Urine had been sugar- and acid-free for 3 days. Diet, carbohydrate 40 gm., protein 44 gm., fat 28 gm.; 588 calories.

64 *N-979*.—Age 50 years, weight 126 pounds. Duration 17 years. Urine, sugar- and acid-free. This sample was taken after treatment to remove sugar from the urine. Diet, carbohydrate 25 gm., protein 28 gm., fat 11 gm.; 311 calories.

108 *M-1025*.—Age 21 years, weight 118 pounds. Duration 1 year. Urine, sugar + and diacetic acid reaction 3 +. Blood sugar 0.28 per cent. Fasting 2nd day.

49 *C-610*.—Age 55 years. Duration 4½ years. Urine, sugar- and acid-free. Blood sugar 0.26 per cent. Hard to keep urine sugar-free. Diet, carbohydrate 1 gm., protein 76 gm., fat 126 gm.; 1,442 calories.

46 *J-436*.—Age 28 years. Duration 7 years. Pregnant (6 months). Urine, sugar- and acid-free. Blood sugar 0.20 per cent. Previously classed as a severe diabetic but the symptoms were relieved by the pregnancy.

85 *O-1005*.—Age 35, weight 74 pounds. Duration 6½ years. Urine, sugar 6 gm. Diacetic acid reaction 3 +. Blood sugar 0.33 per cent. 7th day in hospital during which time the carbohydrate was being cut down. Next day the urine was sugar-free. Diet, carbohydrate 13 gm., protein 4 gm., fat 0; 68 calories.

Sample II. (97 O).—2 weeks later. Urine, sugar- and acid-free. Some edema. The carbohydrate had been cut down to 0, then raised to the present 14 gm.

79 G-996.—Age 63 years, weight 98 pounds. Duration 1 year, 2 months. Urine, acid-free but contains some sugar. Blood sugar 0.40 per cent. Diet, carbohydrate 10 gm., protein 47 gm., fat 33 gm.; 525 calories.

52 Jh-765.—Age 22 years, weight 88 pounds. Duration 1 year, 9 months.

61 Jh-765.—Age 22 years, weight 88 pounds. Duration 1 year, 9 months.

70 Jh-765.—Age 22 years, weight 88 pounds. Duration 1 year, 9 months.

Sample I.—Just entering hospital. Urine, sugar 67 gm. Diabetic acid reaction 3 +.

Sample II. (61 Jh).—Urine contained 23 gm. sugar and gave a 2 + diabetic acid reaction. Diet, carbohydrate 0, protein 40 gm., fat 25 gm.; 385 calories. Blood sugar 0.20 per cent.

Sample III. (70 Jh).—Urine, sugar- and acid-free. Fasting. Blood sugar 0.26 per cent.

60 B-983.—Age 55 years, weight 197 pounds. Duration 6 weeks. Shortly after entering hospital. Diet being gradually reduced. Present diet, carbohydrate 55 gm., protein 26 gm., fat 10 gm.; 414 calories. Urine, sugar 4 per cent; diabetic acid reaction 2 +. Blood sugar 0.33 per cent.

96 H-1011.—Age 27 years, weight 84 pounds. Duration 2 years. Urine, sugar 2.9 gm. Diabetic acid reaction 2 +. Blood sugar 0.23 per cent. Diet, carbohydrate 5 gm., protein 8 gm., fat 0; 52 calories.

Lipemias. /

123 Co.—Just entering hospital. Age 30 years, weight 121 pounds. Duration 1 year. Urine, sugar 4.1 per cent (118 gm.). Diabetic acid reaction 2 +. Blood sugar 0.25 per cent.

124 Cl-786.—This is the same patient as 42 Cl, and the details regarding him are given under that heading.

The results of the analyses are given in the following table.

In the table, the value "total fatty acids" is obtained by subtracting the value for cholesterol from that of "total fat" as determined. The value "fat" represents what is believed to be ordinary fats and includes all the fatty acids except those combined as "lecithin" or as cholesterol esters. The value "total lipoids" (total ether-soluble in earlier papers) is obtained by adding together the values for lecithin, cholesterol and its esters, and fat. The values given for the corpuscles are calculated from corresponding values of whole blood and plasma, taking into account the percentage of corpuscles. In these calculations it is assumed that (1) the "lecithin" is oleo-stearyl lecithin, (2) the cholesterol in the corpuscles is free, and (3) two-thirds of the cholesterol of the plasma is there in combination with the fatty acids (as cholesterol esters).

The cases are arranged in the table approximately in the order of their clinical severity, the mild ones at the beginning and the severe ones at the end. Because of differences in the normal lipid values for men and women separate groups are made and with each group is given the normal values,—average, high, and low as previously determined.³

DISCUSSION.

General.—In the severe diabetics the blood lipoids were all markedly increased—up to 100 per cent or more of the normal values. In the mild cases there may be no increase and in some even a decrease. On the other hand a clinically mild case may show considerable abnormality, due probably to diet, as in 102 St. This person was not under treatment and the only restriction on his diet was that he should keep his urine free from sugar. Between the mild and the severe cases were all degrees of gradation in the blood lipoids, but in general the more severe or long standing the diabetic condition the more marked was the abnormality in the blood lipoids.

No lipemia (cloudiness or milkiness of the plasma) was observed in the thirty-six patients under treatment although many of them were clinically severe. Lipemia was found present in two persons not under treatment, one of these was just entering the hospital for treatment, the other a patient who after discharge had broken diet and returned in a dangerous condition.

Next in importance perhaps to the absolute increase of the blood lipoids was the fact that *the relations between the lipoids were practically the same as in normal individuals*. A certain tendency may, however, be noted which is significant in view of the conditions in lipemia. That is the tendency of the "total fatty acids" to increase out of proportion to the other constituents as shown by the values for the relation $\frac{\text{total fatty acids}}{\text{lecithin}}$

in the plasma, which are almost always at the upper limit of normal variation and frequently above it (especially in men) and also the tendency for the value "fat" in the plasma to be abnormally high (again most noticeable in men)—both of which indicate a tendency for fat to accumulate in the blood.

In diabetic lipemia the greatest increase was in the fat, and the milkiness of the plasma is due mainly if not entirely to finely suspended fat, as indeed has always been believed. What has not been previously appreciated is that the cholesterol increases almost parallel to the fat; in the severest lipemia noted above (124 Cl) it reached over 1.5 gm. per 100 cc. of plasma. On the other hand values for "lecithin" were not greatly increased in

lipemia as shown by the lecithin values in this patient as compared with those without lipemia (42 Cl).

The increases of the blood lipoids in severe diabetes without lipemia and as far as can be determined in diabetic lipemia (the calculated values here are less reliable because of the large amounts involved) occur *only in the plasma*, the composition of the corpuscles remaining practically constant. The same has been found true for other pathological conditions.⁵ These results are in marked contrast to those found in alimentary lipemia.¹¹ Here the "total fatty acids" were increased in both plasma and corpuscles, the increase being rather more marked in the corpuscles. "Lecithin" was increased parallel with the "total fatty acids" but in the corpuscles alone. Cholesterol was not found to change notably. The parallelism between "total fatty acids" and "lecithin" in alimentary lipemia was taken as evidence that "lecithin" is a step in fat metabolism and that its formation takes place in the corpuscles. The constancy of the cholesterol values was believed to indicate that it had no part in the earlier stages of the process. The condition of the lipoids in severe diabetes may therefore probably be regarded as a later stage in fat metabolism than the above. In this stage the corpuscles appear to have no part since their composition remains constant and normal. "Lecithin" continues to be an important factor since it changes parallel with the total fatty acids in all cases but the lipemia. The most marked feature of these later stages is, however, the cholesterol which increases parallel with the total fatty acids even in lipemia. These results give strong support to the assumption made in a previous paper⁵ that cholesterol takes a part and probably an important part in fat metabolism. Because of the constancy of the relation of cholesterol to the other lipoids in the plasma, the determination of cholesterol should give valuable information regarding the lipid content of the blood in diabetes.

The blood corpuscle percentage of the whole blood is normal in all but the severest lipemia.

No definite relation could be discovered in the present work between high blood lipoids and the presence of acetone bodies

¹¹ Bloor, *J. Biol. Chem.*, 1916, xxiv, 447.

in the urine. Thus 63 G with very high blood lipoids had no diacetic acid in the urine, while 43 T with blood lipoids not abnormally high had a strong diacetic acid reaction (4 +) in his urine. Even coma and death may take place (78 A) without marked change in the blood lipoids.

Three members of this series were fat (106 M, weight 222 pounds; 47 D, weight 197 pounds; and 60 B, weight 197 pounds). In all the onset had been recent, less than 2 months. The first two were mild, the third severe.

One member of the series (46 J), previously a severe diabetic, was pregnant at this time and as is frequently the case her symptoms were mild and her blood lipoids were normal.

Lipemia.—The presence of lipemia in severe diabetes is reported so often in the literature that it might almost be regarded as a symptom of the severe type of the disease. It is therefore remarkable that in the series of thirty-six cases reported above none of the patients under treatment showed any lipemia, although many of them were severe. Since the treatment consists of partial or complete fasting, the theory that the excessive blood lipoids in lipemia originate from the mobilization of stored fat as the result of the stimulus of inanition or that they come from the breakdown of tissue cells, appears quite improbable since under the above conditions of treatment fat mobilization or tissue breakdown would be most marked. On the other hand, the two cases in which there was lipemia were not under treatment at the time and were on an unrestricted diet. The one with the severest lipemia was a former patient who, while in the hospital, had been free from lipemia although his blood lipoids were high (42 Cl). On leaving the hospital he had broken diet, eating among other things large quantities of fat (cream). The other had been on an unrestricted diet and at this time was just entering the hospital for treatment. In both the lipemia disappeared when they were put on a fat-free diet. The origin of the lipemia, in these cases at least, appears to be the fat of the diet, and a consideration of the attendant conditions indicates that a similar explanation would account for many of the reported instances of lipemia in the past. The dietary treatment of diabetes up to very recently has been to withhold carbohydrate and make up the caloric deficiency with protein and fat. The resulting overwork of the fat-burning mechanism

would be expected to cause, in some cases at least, a partial failure of the mechanism with an accumulation of fat and its metabolites in the blood. A contributing factor is the lack of available carbohydrate without which complete burning of the fatty acids does not seem to be possible. The high lipid values where there is no lipemia may probably be regarded as an earlier manifestation of the same partial failure of the fat metabolism. The mechanism is still working in an approximately normal manner, since the relations between the lipoids are normal, but the accumulation of the metabolites has begun. In the actual lipemia the mechanism has fallen behind with its work and the raw materials have accumulated until they can no longer be carried in solution in the plasma. That even at this time all parts of the mechanism have not failed is evident from the increase of cholesterol, which keeps pace with the fat. That part of the process, however, which has to do with the formation of lecithin from fat has apparently failed and it is possible that this failure may be the underlying cause of the lipemia. Under former conditions of treatment the chances of recovery of a diabetic with lipemia were generally regarded as poor, as might be expected if the above explanation of the cause of lipemia were true, since the continued diet of fat involved the overloading of an already failing mechanism. In the two cases reported in this paper the lipemia cleared up on a fat-free diet, so that even a severe lipemia apparently need not be serious if the fat of the diet be controlled. The importance of the modification of the treatment to include control of the fat of the diet is obvious. Occasionally lipemia has been reported in diabetes where the blood lipoids were not sufficiently above normal to warrant it. As throwing light on this peculiarity the observation was made several times in the course of this work that a clear diabetic plasma would become milky on standing at room temperature for 24 hours. Bacterial action cannot be excluded but since no such change was found to occur in normal plasma or in the plasma in other pathological conditions, the appearance of the milkiness is believed to be due to an inherent peculiarity of diabetic blood—probably some unstable combination which is broken up on standing. Since many of the examinations on diabetic blood reported in the literature were made on samples which had stood 24 hours or longer, the development of the lipemia post mortem was not unlikely.

SUMMARY.

In severe diabetes the blood lipoids were all markedly increased, up to 100 per cent or more of the normal values. In mild diabetes the lipoids may be normal. In general the more severe or long standing the diabetic condition the more marked was the abnormality in the blood lipoids.

In spite of the high values the relations between the lipoids were practically those of normal individuals, indicating that the fat metabolism was essentially normal. There was a tendency, however, for the fat to accumulate in excess of the other constituents and this fact and possibly also the high lipid values foreshadow the lipemia.

The high lipid values noted occurred entirely in the plasma, the composition of the corpuscles remaining practically normal.

The fact that cholesterol increased parallel with the fat in diabetic blood, even in severe lipemia gives further support to the earlier assumption that cholesterol has a part and probably an important part in fat metabolism. For the same reason the determination of cholesterol in the plasma (a relatively simple process) should give valuable information regarding the lipid content of the blood in diabetes.

In the present series no definite relation could be found between high blood lipoids and the occurrence of acetone bodies in the urine.

Lipemia.—Lipemia was observed in but two of the thirty-six cases in this series and these were not under treatment but were on an unrestricted diet. No lipemia was found in any of the cases under treatment. Evidence is presented to indicate that diabetic lipemia originates mainly in the fat of the food and that the probable reason for its appearance in the blood is a partial failure of the mechanism for dealing with fat. Cholesterol increases parallel with the fat up to eight times its normal value while lecithin is relatively little increased. Since lecithin formation has been found to be an early stage in the metabolism of fat it is possible that the inability to form lecithin may be a factor in the production of the lipemia.

THE CHEMICAL NATURE OF THE "VITAMINES."

II. ISOMERISM IN NATURAL ANTINEURITIC SUBSTANCES.

BY ROBERT R. WILLIAMS AND ATHERTON SEIDELL.

(From the Bureau of Chemistry, United States Department of Agriculture,
and the Hygienic Laboratory, United States Public Health Service,
Washington, D. C.)

(Received for publication July 14, 1916.)

PLATE 2.

Recent investigations by one of us¹ demonstrated a dynamic isomerism in the hydroxy pyridines which has a most profound influence upon the antineuritic properties of these substances. This rather remarkable fact suggested that a similar isomerism may exist in the natural "vitamines" and be responsible for the instability which has so far prevented their isolation. With this conception in mind, attention was directed to the natural antineuritic substances of yeast, and results have been obtained which strengthen the conjecture that an isomerism plays a determinative rôle in the physiological action of the natural "vitamines" not less striking than in the hydroxy pyridines.

A great obstacle confronting previous investigators of "vitamines" has been the difficulty of securing adequate amounts of sufficiently concentrated products for experimental study. Since it had been shown by one of us² that the antineuritic substances of autolyzed yeast are completely adsorbed and retained in a physiologically active condition by fullers' earth, we considered that this solid combination of relatively pure "vitamine" and an inert inorganic substance would offer greater advantages for this study than any product previously available. Its preparation is extremely simple and it can be obtained in amounts limited only by the supply of yeast at hand. There is practically no loss of active "vitamine" in the process of "activating" the

¹ Williams, R. R., *J. Biol. Chem.*, 1916, xxv, 437.

² Seidell, A., *U. S. Pub. Health Reports*, 1916, xxxi, 364.

solid, and the small amount of other substances adsorbed simultaneously with the "vitamine" do not appear to be of noteworthy consequence.

Our first problem was to effect a separation of the "vitamines" from the fullers' earth. Since fullers' earth had previously been used for the isolation of alkaloids³ and the alkaloids subsequently recovered from the solid combination by means of alkali, it was expected that in the case of the "vitamine" combination, alkali could be successfully used. However, since it is generally believed that alkalis have a destructive effect on "vitamines," it was decided first to attempt extraction with other than alkaline solvents. Attention was therefore turned to the use of acidified aqueous alcohol. In general, the experiments indicated that the antineuritic substances could be partially extracted by acid alcohol but subsequent manipulation of this extract was complicated by the presence of large amounts of acid alcohol-soluble aluminium compounds.⁴ These substances so contaminated all antineuritic fractions that no ash-free curative product could be obtained and the method was abandoned chiefly on that account.

The Effect of Alkalis on Vitamines.

Some evidence was early encountered that the "vitamines" of autolyzed yeast are not decomposed by alkali as readily as previously supposed. In a preliminary experiment, solid sodium hydroxide was dissolved in autolyzed yeast filtrate to the extent of 10 per cent by weight, the resulting alkaline solution was allowed to stand at room temperature for 5 hours and then neutralized with hydrochloric acid. On administering this solution to polyneuritic pigeons it was found that its curative properties apparently had suffered very little by the treatment. This appeared to contradict past evidence of the destructive effect of alkali⁵ and it was therefore decided to conduct more extended experiments to settle this point. In the case of autolyzed yeast

properties observable in this case possibly is due to a different type of cleavage. (We recognize that this change in properties is equally well accounted for by other assumptions such as that of the existence of two types of "vitamines" only one of which is destroyed by alkali.⁷)

Further, we have evidence that "vitamines" can be reduced to still simpler compounds which are physiologically active. Although the antineuritic properties of foodstuffs and of crude extracts persist through long periods of storage, it has been the experience of investigators who have attempted to isolate the "vitamines" that the final relatively purified fractions are apparently much less stable, since simple recrystallization may often serve to destroy the curative property. Later in this paper evidence will be presented that certain fractions of yeast may automatically lose their curative property when they are allowed to stand a few days at ordinary temperature.

These facts suggest the following hypothesis which is in part a restatement of old conceptions. The "vitamines" contain one or more groups of atoms constituting nuclei in which the physiological properties are resident. In a free state these nuclei possess the "vitamine" activity but under ordinary conditions are spontaneously transformed into isomers which do not possess antineuritic power. The complementary substances or substituent groups with which these nuclei are more or less firmly combined in nature exert a stabilizing and perhaps otherwise favorable influence on the curative nucleus, but do not in themselves possess the "vitamine" type of physiological potency. Accordingly it is believed that while partial cleavage of "vitamines" may result only in a modification of their physiological properties, by certain means disruption may go so far as to effect a complete separation of "nucleus" and "stabilizer," and if it does so will be followed by loss of curative power due to isomerization. The basis for the assumption that an isomerization constitutes the final and physiologically most significant step in the inactivation of a "vitamine" is found in studies of synthetic antineuritic products.¹ This assumption is supported by evidence, to be presented later in this paper, of the existence of such an isomerism in the crystalline antineuritic substance obtainable from brewers' yeast.

⁷ McCollum, E. V., and Davis, M., *J. Biol. Chem.*, 1915, xxiii, 181, 231.

filtrate, Feeding Experiments 1 and 2 (Chart I) show no noticeable alteration of physiological activity resulting from a rather severe treatment with alkali. However, fullers' earth, "activated" by shaking with autolyzed yeast, suffered a certain modification of its physiological action when subjected to similar treatment (Feeding Experiments 3 to 6 inclusive, Charts II and III.) It was found that this product, though absolutely preventing the development of polyneuritic symptoms in birds fed on an exclusive diet of polished rice, failed to protect them against loss in weight. Therefore it appears that the complete physiological activity of the constituents of autolyzed yeast adsorbed by fullers' earth is a combination of antineuritic and weight-maintaining functions, and it is the latter only which is materially affected by alkalis under the conditions of the present experiments. Whatever the explanation of this phenomenon may be, we feel justified in concluding that such a product as that used in Feeding Experiment 6 still contains a substance which is essentially of a "vitamine" nature.

*Theoretical Considerations Concerning the Chemical Nature of
"Vitamines."*

Numerous writers have held the view that the "vitamines," by which term we mean certain constituents of untreated food-stuffs, are complex compounds. Accordingly various investigators have submitted products to autolysis or hydrolysis with mineral acids as a preliminary to chemical investigation, the object of such treatment being to reduce the complex natural compounds into simpler ones which possess at least the more essential physiological characteristics of the parent substances. That hydrolysis with mineral acids does effect some change in the "vitamines" is definitely proved by the fact that extract of rice polishings, after hydrolysis, has a distinctly altered physiological action, being much more efficacious as a curative agent than the original extract.⁶ It is only reasonable to suppose that this change results from cleavage of the original molecules. The evidence we have obtained regarding the effect of alkalis on "activated" fullers' earth suggests that the alteration of physiological

⁶ Vedder, E. B., and Williams, R. R., *Philippine J. Sc., B.*, 1913, viii, 175. Williams, R. R., and Saleeby, N. M., *ibid.*, 1915, x, 99.

subsequently with alkali a deep blue color is produced. It has been our experience that a negative test for this color indicates the absence of the curative substance in crude solutions. A positive reaction can with less assurance be taken to indicate the presence of the "vitamine."

The application of this test afforded further evidence suggestive of isomerism. The original liquid from which the needle crystals are deposited gives an intense Folin-Macallum reaction. After crystallization has taken place the mother liquor responds to the test much less strongly and the crystals, as first obtained, respond only slightly and not at all after recrystallization. The property of producing an intense blue coloration with phosphotungstic acid can be imparted to the crystalline substance by simple means. Still more convincing is the fact that by suitable treatment the completely non-curative recrystallized substance is converted into products which show distinct antineuritic properties. The quantity of substance so far available has not been adequate to permit an attempt to isolate these reaction products.

Funk has recently found adenine in the acetone-insoluble fraction of the phosphotungstates of autolyzed yeast.¹⁰ Possibly because it is a well known constituent of yeast which he had previously tested for antineuritic properties with negative results¹¹ he apparently did not regard it as being connected in any way with the active substance. The fact that the curative fractions of yeast obtained by such diverse methods both yield adenine in relatively large quantities in itself argues that the adenine found is closely related to the curative substance, and gives further weight to our conclusion.

We regard the work presented in this paper of chief interest not in its contribution toward establishing the composition or identity of this "vitamine," which may or may not be a unique compound, but in affording corroboration of the theory advanced elsewhere that an isomerism plays a determinative rôle in the physiological potency of "vitamines." The striking isomerism of 4-phenyl-isocytosine¹² suggests itself as possibly similar to that

¹⁰ Funk, C., *Biochem. Bull.*, 1916, v, 1.

¹¹ Funk, J. *Physiol.*, 1912-13, xlv, 489.

¹² Warmington, E., *J. prakt. Chem.*, 1893, xlvii, 214. Johnson, T. B., and Hill, A. J., *J. Am. Chem. Soc.*, 1914, xxxvi, 1201.

lize a free or combined curative nucleus before it has opportunity to isomerize into a non-curative substance; or, second, to isolate this nucleus in an inactive form and convert it into the active isomer, thus proving that it is related to the original antineuritic substance. Experiments which will be described in the following pages show that a measure of success has been attained in both of these directions.

Fractionation of an Alkaline Extract of "Activated" Fullers' Earth.

From an extract obtained by shaking "activated" fullers' earth with a 5 per cent solution of sodium hydroxide in dilute alcohol a crystalline substance was separated in the form of clumps of fibrous needles of such minute size as to be indistinguishable under the lower powers of the microscope (Fig. 1). These crystals were surprisingly uniform in appearance, free from coloring matter, and possessed very distinct antineuritic properties. When a dilute aqueous solution of the crystals is slowly evaporated the compound crystallizes in small rather irregular pyramids which melt at 345° (uncorrected). When they are dissolved in a minimum quantity of hot water and the solution is rapidly cooled, the greater part of the substance crystallizes in needles resembling the original in crystal form. In both cases the recrystallized product possessed no curative or protective power and proved to be identical with adenine. The activity of the original needles can scarcely have been due to adhering mother liquor for the mother liquor itself was much less curative than the crystalline substance. The original needles rapidly lost their curative power after drying but retained it when kept in contact with the mother liquor. These observations led us to believe that an isomer of adenine is the chemical entity which is responsible for the characteristic physiological activity of the curative crystalline product.

In the course of the experiments on the isolation of antineuritic products extensive use has been made of the Folin-Macallum¹ phosphotungstic acid reaction as a guide in following the physiologically active substance. When autolyzed yeast or similar antineuritic products are treated with phosphotungstic acid and

¹ Folin, O., and Macallum, A. B., *J. Biol. Chem.*, 1912, xi, 265; 1912-13, xiii, 363. Funk, C., and Macallum, A. B., *Biochem. J.*, 1913, vii, 356.

subsequently with alkali a deep blue color is produced. It has been our experience that a negative test for this color indicates the absence of the curative substance in crude solutions. A positive reaction can with less assurance be taken to indicate the presence of the "vitamine."

The application of this test afforded further evidence suggestive of isomerism. The original liquid from which the needle crystals are deposited gives an intense Folin-Macallum reaction. After crystallization has taken place the mother liquor responds to the test much less strongly and the crystals, as first obtained, respond only slightly and not at all after recrystallization. The property of producing an intense blue coloration with phosphotungstic acid can be imparted to the crystalline substance by simple means. Still more convincing is the fact that by suitable treatment the completely non-curative recrystallized substance is converted into products which show distinct antineuritic properties. The quantity of substance so far available has not been adequate to permit an attempt to isolate these reaction products.

Funk has recently found adenine in the acetone-insoluble fraction of the phosphotungstates of autolyzed yeast.¹⁰ Possibly because it is a well known constituent of yeast which he had previously tested for antineuritic properties with negative results¹¹ he apparently did not regard it as being connected in any way with the active substance. The fact that the curative fractions of yeast obtained by such diverse methods both yield adenine in relatively large quantities in itself argues that the adenine found is closely related to the curative substance, and gives further weight to our conclusion.

We regard the work presented in this paper of chief interest not in its contribution toward establishing the composition or identity of this "vitamine," which may or may not be a unique compound, but in affording corroboration of the theory advanced elsewhere that an isomerism plays a determinative rôle in the physiological potency of "vitamines." The striking isomerism of 4-phenyl-isocytosine¹² suggests itself as possibly similar to that

presumed to exist in adenine. Studies of synthetic preparations of both substances will be undertaken shortly in order to test the correctness of this view.

EXPERIMENTAL PART.

Brewers' yeast was autolyzed and filtered, and each liter of the filtrate so obtained was shaken with 50 gm. of specially prepared fullers' earth (Lloyd's reagent) kindly furnished us by Professor J. U. Lloyd. The procedure followed in these operations has been described in a recent paper by one of us.² The autolyzed yeast filtrate so prepared is curative for polyneuritis in pigeons in doses of 1 cc. 50 mg. of the "activated" fullers' earth has an approximately equivalent antineuritic potency. Analysis of such "activated" earth by the Kjeldahl method indicated the presence of 2.6 to 3.0 per cent of nitrogen.

In each of the feeding experiments described in the following pages the pigeons were kept in cages in groups of six to ten and supplied only with polished rice and water. Each bird was weighed every 2nd or 3rd day, and immediately thereafter given by mouth the liquid or solid material being tested for its "vitamine" character. On account of the variation in eating habits of the pigeons the daily fluctuations in weight were large and the weight curves show corresponding irregularities. It is therefore only the grosser changes in weight which are significant. In order to make a comparison of the several birds, the ordinates in all charts represent the observed weights expressed as per cent of the previously determined normal weight of the bird on a mixed diet. The abscissæ in all cases represent the number of days the experiment had progressed. Ordinarily controls of each group of birds were not kept since a large number of control experiments had previously been made and the effect of an exclusive diet of polished rice was fairly definitely known.

Acid Extraction of "Activated" Fullers' Earth.

100 gm. of "activated" fullers' earth were digested for 5 hours on a steam bath under a reflux condenser with 200 cc. of 50 per cent alcohol containing approximately 10 per cent by weight of hydrochloric acid. The hot mixture was rapidly filtered through a layer

of asbestos by the use of suction. The filtrate was evaporated to dryness under diminished pressure. The dark residue was dissolved in water and the solution filtered. 2 cc. of the filtrate corresponding to about 2 gm. of "activated" earth caused no improvement in a paralyzed pigeon and the bird died within about 10 hours (S 110). The solution was evaporated to dryness in a vacuum desiccator and yielded a greenish gray residue, 10 mg. of which produced undoubted improvement in a completely prostrated pigeon (S 140). This residue was found to be almost completely soluble in absolute alcohol. On pouring the alcoholic solution into ethyl ether, a very voluminous light colored precipitate separated. This was collected on a filter, washed with ether, and dried in a vacuum desiccator. 10 mg. of the resulting brittle dark gray product relieved the paralysis in a pigeon (W 82) but the bird remained stupid and weak and died on the 5th day. A larger quantity of this ether-insoluble material was prepared and thoroughly dried in a vacuum desiccator. It was found to be extremely hygroscopic, yielded copious amounts of free hydrochloric acid vapors on exposure to the air, and on ignition left a large quantity of inorganic residue, principally alumina.

Another 100 gm. lot of "activated" fullers' earth was extracted as in the first experiment. The extracted solid after washing several times on the filter was dried and 0.1 gm. administered to a polyneuritic pigeon (S 157). The results indicated that the solid still retained a considerable amount of active material.

The extract obtained from the above digestion was evaporated to dryness under diminished pressure as before. The residue was extracted several times with warm acetone which dissolved only a relatively small part of it. The acetone-insoluble residue was taken up in about 50 cc. of absolute alcohol and the filtered solution was concentrated on a hot plate to about 20 cc. On standing over night a fairly uniform deposit of cubical crystals was obtained. These were very soluble in water and alcohol and on drying gave off hydrochloric acid and lost their crystalline character. Their properties appeared to correspond in general to those of hydrated chlorides of aluminium as described by Moissan.⁴ It is therefore probable that the product resulting from acid alcohol extraction of "activated" earth consists largely of aluminium chloride as such or as double salts with alkalis. Since the products

showed physiological activity it is evident that minute amounts of antineuritic material accompanied the inorganic salts. An attempt to separate the "vitamine" from the inert material by precipitating the alumina with ammonia yielded a filtrate in which no antineuritic activity could be detected.

The Effect of Alkalis on the "Vitamines" of Autolyzed Yeast.

(a) A quantity of physiologically active autolyzed yeast filtrate was divided into two equal portions. One portion was treated with alkali on March 7 as described below and used for administration to a group of birds during the period from March 7 to May 8 (Pigeons S 128, 137, and 140, Chart I). The second portion was reserved for the treatment of Pigeons S 130, 131, and 148 (Chart I), aliquots of the liquid being withdrawn on the days the pigeons were dosed, and treated with alkali in the same manner immediately before administration. The pigeons received the respective liquids on alternate days in amounts equivalent to 3 cc. of the original yeast filtrate. In every respect the two groups were treated alike except that in one case the birds received a product treated with alkali some time in advance and in the other they received the same product freshly prepared from day to day during the progress of the feeding test. The method of treating with alkali was as follows: Sufficient 50 per cent sodium hydroxide solution was added to a known volume of autolyzed yeast filtrate to give a concentration of 5 per cent by weight of sodium hydroxide in the mixture. The alkaline solution was allowed to stand 5 hours at room temperature, faintly acidified with a measured quantity of hydrochloric acid, and filtered.

The animals in both groups showed no detectable impairment of health or vigor and with the exception of one bird in each group maintained approximately normal weight during the entire 60 day period of the experiment, as shown in Chart I. The loss in weight in the case of the two birds amounted to only about 15 per cent. It is therefore apparent that the "vitamine" in autolyzed yeast is not appreciably affected by being kept in a 5 per cent caustic solution at room temperature for a period of 5 hours.

(b) 50 gm. of "activated" fullers' earth were shaken with 200 cc. of 5 per cent aqueous sodium hydroxide and allowed to stand in

contact with the alkaline liquid for 5 hours. A slight excess of hydrochloric acid was then added to the suspension and the mixture shaken and filtered. The solid, which should have reabsorbed all unchanged "vitamines" from the acidified solution, was administered every 2 or 3 days to Pigeons S 149 and 150 in doses of 0.15 gm. (Chart II). Although the birds were reduced to about 75 per cent of their original weight, no polyneuritic symptoms developed and they seemed as healthy and active as normal ones up to the end of the experiment.

(c) The above experiment was repeated with the modification that the "activated" earth was allowed to stand in contact with the alkaline liquid for only 10 minutes. After acidifying and filtering, the solid residue was used for treating Pigeons S 153 and 154 (Chart II), and the filtrate was given to two others (Nos. S 155 and 156, Chart II), the dosage at 2 or 3 day intervals in each case being equivalent to 0.15 gm. of the original "activated" earth. The solid residue as before afforded complete protection against any symptoms of disease and in addition the loss in weight was much less than in the previous experiment. In the case of Birds S 155 and 156 which received the filtrate, the loss in weight and development of polyneuritis showed that practically all of the "vitamine" had been reabsorbed by the fullers' earth on acidifying the alkaline mixture. Since in both cases of the birds receiving the solid which had been treated with alkali, no polyneuritic symptoms developed, it is apparent that alkali had not affected the antineuritic properties of the solid. The marked losses in weight show that some alteration of the adsorbed "vitamine" had occurred.

(d) 100 gm. of "activated" fullers' earth were shaken with 500 cc. of 5 per cent aqueous sodium hydroxide solution for 10 minutes. The mixture was filtered with the aid of suction and the filtrate slightly acidified with hydrochloric acid. A yellowish precipitate separated and this was removed by filtration. The solution so obtained was used for treating two birds, Nos. S 151 and 152 (Chart III). Each bird received by mouth every 2 or 3 days an amount of the neutralized alkaline extract equivalent to 0.15 gm. of the original "activated" earth. The birds lost only about 10 per cent in weight and apparently remained in perfect health during the 50 days of the experiment. Therefore it may be

concluded that by rapid extraction of "activated" fullers' earth with 5 per cent caustic alkali, the adsorbed "vitamine" can be removed without materially diminishing its physiological potency. This was a very important point to settle since the method for isolating crystalline antineuritic substances described in the following section is based upon the alkaline extraction of the "activated" solid.

Fractionation of Alkaline Extract of "Activated" Fullers' Earth.

(a) 200 gm. of "activated" fullers' earth were shaken vigorously for 15 minutes with 400 cc. of 5 per cent aqueous sodium hydroxide solution. The liquid was filtered with the aid of suction and the solid residue was shaken with 400 cc. of 95 per cent alcohol and the suspension was filtered as before. The combined aqueous and alcoholic filtrates were neutralized with glacial acetic acid. This produced a small flocculent precipitate which was separated by filtration and discarded. The reddish brown filtrate gave a strong Folin-Macallum reaction. An amount of it equivalent to 90 mg. of the original activated earth was administered to a polyneuritic pigeon (W 85). The next day the bird was apparently normal and 15 days elapsed before the return of the symptoms. Another extract similarly prepared gave like results with another bird (W 66).

A saturated aqueous solution of mercuric acetate was added to the above filtrate as long as any precipitation was produced. The mercuric acetate precipitate was separated with suction and dried on a porous plate. When air-dried the product weighed 18 gm.

Hydrogen sulfide was passed into the filtrate from the mercuric acetate precipitate. After removal of the resulting mercuric sulfide by filtration and expulsion of the excess of hydrogen sulfide by boiling *in vacuo*, the liquid gave a moderate Folin-Macallum reaction. A large dose equivalent to 0.8 gm. of the original activated earth was administered to a polyneuritic pigeon (W 100). The bird gradually improved and lived 12 days but at no time regained full use of its legs and wings. Accordingly this fraction was not investigated further.

The dried mercuric acetate precipitate was finely ground,

suspended in 150 cc. of water containing 5 cc. of glacial acetic acid, and decomposed with hydrogen sulfide. The mercuric sulfide was removed by centrifugation and extracted four times by maceration with portions of 100 cc. of water containing hydrogen sulfide. The combined extracts were filtered and boiled *in vacuo* to expel hydrogen sulfide. A portion of the solution was reserved for tests of its antineuritic properties. On the 1st day after preparation a dose equivalent to 0.09 gm. of original activated earth was given to a polyneuritic bird (W 88). It had recovered completely from the paralysis the following day, became alert and active, gained 15 gm. in weight, and lived 18 days before return of severe symptoms. This indicated that mercuric acetate precipitates the larger part of the antineuritic substance. When 8 days old the same solution in the same quantity was administered to another polyneuritic bird (W 97). The bird recovered from the severe paralysis but remained slightly stupid and redeveloped symptoms after 8 days. The maximum gain in weight was only 7 gm. though the bird was thin when treated. When the solution was 13 days old an equal dose was given a third bird (W 99). No improvement resulted nor did the bird recover after a second equal dose given on the following day. It died 3 days after the first treatment. Although only three birds were involved in these experiments they appear to indicate a loss of curative power with lapse of time.

Meanwhile without unnecessary delay, the main portion of the filtrate from the mercuric sulfide was evaporated *in vacuo* to a volume of 50 cc. during which process about 0.5 gm. of a granular brownish substance separated. The substance was removed by filtration, washed with water, and recrystallized from hot water. It proved very sparingly soluble in cold water and only slightly in hot. After recrystallization the substance was still not of a uniform appearance, consisting of irregular warts and pyramids mixed with whetstone-shaped crystals. It decomposed above 330°, gave no Folin-Macallum reaction either directly or after treatment with acids (compare below), and showed no evidence of curative properties. Inasmuch as the product was evidently a mixture of difficultly soluble substances which could not be resolved into purer fractions by simple recrystallization, it was not studied further.

The filtrate from this substance was placed in a vacuum desiccator over sulfuric acid. The following day the liquid was covered with a white crust beneath which was a magma of material of fibrous texture. The crust was separated mechanically as completely as possible and the magma of crystals underneath removed by filtration. The combined weight of both forms was 0.85 gm. Under the microscope the crust was seen to be made up of colorless warts. The underlying material was nearly white and proved to consist of rosettes of extremely fine fibrous needles, which could be distinguished only under the higher powers of the microscope. The material was strikingly uniform in appearance. Both the crust and the fibrous needles gave only a faint Folin-Macallum reaction and the filtrate from them also gave this reaction moderately, though the liquid had done so intensely before crystallization began. The fresh needles were found to possess a marked curative power. One pigeon (W 94) in a severely paralyzed condition received an injection of 1 mg. in water solution. It showed improvement within 2 hours, recovered completely from paralysis, and was able to fly the following day. A day later another bird (W 101) developed symptoms and was given an injection of a water solution of 2 mg. of the needles. The following day it had recovered completely, gradually gained 42 gm. in weight, and lived 12 days. On the 4th day after separation of the needles a bird (W 102) was dosed similarly and improved considerably though less than the birds previously treated, but lived 17 days. On the 7th day another pigeon (W 98) after an injection of 2 mg. improved slightly but gained no weight, and died the 3rd day. It was later found that the material had lost its crystalline form and had become amorphous.

2 mg. of the mother liquor 2 days after separation of the needles were administered by injection to a polyneuritic pigeon (W 93). An extremely slight improvement followed. A second dose of 3 mg. the following day produced no visible result and death followed within a few hours.

The needles after drying over night in a vacuum desiccator melted with decomposition at 318° (uncorrected), and dissolved in hot concentrated sulfuric acid with the production of a slight violet color. They were sparingly soluble in cold water but readily in hot. In alcohol they dissolved less freely than in

water at corresponding temperatures. When recrystallized from water by the evaporation of a dilute solution *in vacuo* over sulfuric acid, the substance yielded irregular pyramids melting fairly sharply at 345° (uncorrected) with decomposition and partial sublimation.

The crusty material referred to above also yielded this product when recrystallized in the same way. On recrystallizing the pyramids (melting point 345°) from a small amount of hot water rosettes of fine needles were obtained from the rapidly cooled solution. Evidently the substance crystallizes in two forms, one of which, the needles, contains water of crystallization. A quantitative determination of the water was not attempted since a product wholly free from pyramids was not obtained.

The recrystallized needles showed no antineuritic properties as indicated by curative tests on polyneuritic birds (W 95 and 106). The pyramids (melting point 345°) possessed no curative or protective properties (Birds S 116, 119, 123, and 125, Chart IV). Neither form as obtained by recrystallization yielded a blue coloration with phosphotungstic acid and alkali. After boiling for an hour or more with glacial acetic acid, acetic anhydride, or dilute hydrochloric or sulfuric acid, both forms gave this reaction intensely. Prolonged standing at ordinary temperatures in mineral acid solution also imparted to them the power to give the coloration. When heated a moment with concentrated sulfuric acid to the boiling point little charring resulted. After diluting, the addition of the Folin-Macallum reagent produced a blue color of extraordinary intensity. The fused and partially charred pyramids also gave this reaction strongly.

The filtrate from the original needles and crusts and the first mother liquors from recrystallization of these substances on slow evaporation in a vacuum desiccator left a residual syrup, in which in course of 10 days a quantity of large rather short needles appeared. They proved extremely soluble in water. Addition of non-aqueous solvents to the mixture of needles and syrup caused the deposition of gum upon the crystalline material and a satisfactory separation could not be effected by this means. By repeated pressing of the syrupy crystalline mass between moist filter papers a small fraction of the crystals was obtained in a perfectly

white condition. The crystals so separated were still sticky with adhering mother liquor and contained a little ash. No evidence of curative power was obtained nor did the substance produce more than a faint blue color with phosphotungstic acid under any conditions.

(b) In a second experiment 200 gm. of "activated" fullers' earth were shaken vigorously for 10 minutes with 500 cc. of 50 per cent alcohol containing 5 per cent sodium hydroxide, and filtered. The residual earth was washed with a further portion of 300 cc. of 50 per cent alcohol. The combined filtrate and washings were neutralized with hydrochloric acid. A yellow granular precipitate separated on standing and was removed by filtration. The filtrate which yielded an intense blue color on treatment with phosphotungstic acid and sodium carbonate was evaporated *in vacuo* to about 150 cc., and filtered from a further granular deposit. It was then evaporated *in vacuo* to dryness and the mass was extracted with 90 per cent alcohol leaving a residue consisting largely of sodium chloride. The alcoholic extract was concentrated *in vacuo* to a volume of about 25 cc. and placed in a vacuum desiccator over sulfuric acid. A magma of rosettes of fine needles was deposited. They were evidently identical with the product previously obtained but were more contaminated with foreign crystalline substances and a brown coloring matter. Since the aggregates were composed of fibrous needles radiating in all directions from a common center, the microscope could not be focused so as to show the whole of any rosette at one time. On this account and because of the fineness of the needles it was not possible to make a satisfactory photograph. A drawing which is reproduced herewith (Fig. 1) was made with the aid of a camera lucida and illustrates the appearance of the rosettes as seen by varying the focus while looking through the microscope.

The bulk of the mother liquor was removed by centrifugation. The mass of crystals was kept in the condition in which it was deposited in the centrifuge tube, the supernatant liquid being merely drained off as completely as possible. In this condition the needles appear to retain their characteristic crystal form indefinitely. When kept in this state they proved capable of curing polyneuritic birds and preventing the recurrence of the symptoms for about 45 days, which was as long a period as it was thought

desirable to continue the experiment (Chart IV). Such birds increased markedly in weight and after more than 80 days on a white rice diet had a normal appearance. Weight was maintained at about 80 per cent of the normal when doses of 10 mg. of the moist crystals were given every 2 or 3 days. In one case (Bird S 121) the dose was increased to 50 mg. (see arrow, Chart IV) given at the same intervals. This pigeon regained its original weight in about 30 days. It then developed ulcerations and swellings in the mouth and being unable to eat began to decline in weight rapidly. It was killed after having lived a total of 73 days on a white rice diet. Healthy birds fed on white rice and given an occasional dose developed no symptoms of disease. However, weight was maintained only on a subnormal plane when doses of 5 to 10 mg. were given by mouth every 2nd day (Chart V).

(c) Since this method of isolating the crystalline product was much shorter and more convenient than that involving the use of the mercuric acetate, it was adopted for the preparation of a sufficient quantity of the crystals for purification and chemical analysis. During the course of this work it was found that while aqueous sodium hydroxide appears to extract the antineuritic substance more completely, it has the disadvantage of yielding much more highly colored extracts which usually crystallize very slowly if at all. On the whole, alkaline 50 per cent alcohol seems most satisfactory.

A quantity of the crude crystalline product so obtained weighed 2.7 gm. It was recrystallized once from water by rapid cooling of a concentrated solution and deposited largely in the form of rosettes of needles. It was then recrystallized once from hot absolute alcohol in which it dissolved sparingly, once from 2 per cent acetic acid, then dissolved in dilute hydrochloric acid and precipitated with an excess of ammonia, and finally fractionally recrystallized twice from water. During this process we had occasion to regret our decision to omit the mercuric acetate precipitation, as it was found difficult to purify this product by crystallization. The final purest fraction weighed 1.07 gm., was nearly pure white, and consisted almost exclusively of the needle form. It was free from ash and after drying at 130° melted at 340° (uncorrected). After drying at 110–115° *in vacuo* it was submitted to analysis.

	<i>per cent</i>
C	43.23
H	4.13

Determinations of nitrogen by the Kjeldahl method gave 49.57 and 49.31 per cent N.

A sample of the product as analyzed for carbon and hydrogen was dried further *in vacuo* at 130° for 3 hours. It lost 1.8 per cent in weight. Correcting the above analysis for moisture the figures obtained are:

	<i>per cent</i>
C	44.02
H	4.00

A similar moisture determination on the sample as submitted to the Kjeldahl method indicated the presence of 2.08 per cent of moisture, the substance having gained in weight on standing in a desiccator over calcium chloride. Corrected for moisture the above figures become 50.62 and 50.36 per cent of nitrogen respectively.

A sample of the substance was placed in a small tube and dried *in vacuo* at 130°, the tube being closed tightly with a rubber stopper on removal from the oven. After cooling, the substance was quickly transferred to a boat and placed in the combustion furnace, the weight being taken by difference. The result of the analysis was:

	<i>per cent</i>
C	43.82
H	4.22

Nitrogen determinations by the Kjeldahl method on the product dried in the same way gave 50.62 and 50.55 per cent respectively.

These analyses are in substantial accord with the corrected analyses recorded above and suggest that the substance is an impure monoamino purine.

	C	H	N
Calculated	44.41	3.73	51.86

A portion of the substance was dissolved in hot water and precipitated with aqueous picric acid solution. A crystalline picrate was obtained in the form of silky needles. These were twice recrystallized from hot water without apparent change of crystal

form. When rapidly heated they began to darken at 280° and melted sharply with complete charring and marked effervescence at $296-297^{\circ}$. A sample of adenine picrate from adenosine, kindly furnished us by Dr. P. A. Levene, showed precisely the same behavior. Mixtures of our picrate with that obtained from Dr. Levene gave a melting point which did not differ from that of either substance separately. We found that the decomposition, which begins at about 280° , takes place far from sufficiently sharply to be characteristic.

A few mg. of adenine were prepared from Dr. Levene's picrate by extracting the picric acid with ether from a hydrochloric acid solution and precipitating the base with ammonia. So prepared it responded to the Folin-Macallum reaction in precisely the same way and under the same conditions as did our substance melting at 345° . The application of Kossel's test¹³ also confirmed the identity of the two substances.

(d) Since fusion and treatment with acids gave this substance the power to produce a blue color with phosphotungstic acid, it was of interest to test the antineuritic properties of the material so treated. In three cases from 5 to 20 mg. of the non-curative substance as submitted to analysis were fused *in vacuo* in small tubes. The contents of the tubes were then removed, suspended in cold water, and administered to three polyneuritic pigeons. Bird W 92 was markedly improved but died the 3rd day; W 96 became bright and lively and lived 7 days; W 97 (second onset) did not improve.

In two experiments small amounts of the substance were boiled with 10 per cent sulfuric acid for 3 hours. The sulfuric acid was then removed by treatment with calcium carbonate and the resulting solutions which gave a marked Folin-Macallum reaction were given to two pigeons (W 85 and 99) by mouth. No benefit was observed in either case.

The general methods used by Johnson and Hill for producing isomers of 4-phenyl-isocytosine¹² were applied to the substance. 10 mg. were heated with 1 cc. of absolute alcohol in a sealed tube to 180° for 3 hours. On cooling, only traces of crystallization took place on standing 48 hours. The tube was then opened and the

¹³ Kossel, A., *Z. physiol. Chem.*, 1888, xii, 241. Fischer, E., *Ber. chem. Ges.*, 1897, xxx, 2226.

contents, diluted with five volumes of water, were administered by mouth to a severely paralyzed pigeon (W 109). The following day it could run about freely but could not fly. Death followed 3 days later. Three other birds (W 115, 116, and 117), similarly treated, all showed distinct improvement and lived 8, 8, and 9 days respectively. 50 mg. of the non-curative substance were heated at 100° for 5 hours with 5 cc. of absolute alcohol in which 10 mg. of metallic sodium had been dissolved. The resulting orange liquid was evaporated to dryness on the steam bath. A polyneuritic pigeon (W 114) received an injection of 5 mg. of the residue dissolved in cold water immediately before administration. Improvement was noticeable in 3 hours. The following day the bird could run and fly freely and showed no symptoms of neuritis. It gained 10 gm. in weight during the 1st day but then declined and became severely paralyzed on the 4th day. It was again treated with a fresh preparation identical with the one previously used and again recovered from paralysis, gained 25 gm. in weight, and again declined and died with typical symptoms on the 8th day after the first onset. Bird W 115a similarly treated was much improved in general condition and gained 20 gm. in weight but did not recover entirely from paralysis. Severe symptoms returned on the 3rd day and the bird was repeatedly dosed with autolyzed yeast filtrate. This did not serve to improve its condition more markedly than had the previous treatment and it seems probable that this individual was suffering from nerve lesions too deep seated to permit of a rapid cure. Bird W 118 was also treated with the sodium ethylate product and recovered very strikingly from severe paralysis and, though it gradually lost 18 gm. in weight, lived 11 days. In every case improvement followed treatment with this product and in some cases the changes in the condition of the birds were of an exceptional character.

It was found that if the residue from the above sodium ethylate treatment was treated directly with phosphotungstic acid, followed by sodium carbonate to render the solution again alkaline, an intense blue color developed. A portion of the residue carefully neutralized with hydrochloric acid also produced marked coloration on addition of phosphotungstic acid and sodium carbonate. When, however, a large excess of hydrochloric acid was added to

the residue scarcely a trace of color was produced on subsequent treatment with the *Folin-Macallum reagent*.

Our supply of purified base as well as that of authentic adenine was exhausted by these experiments.

SUMMARY.

1. The physiological properties of autolyzed yeast filtrate were not appreciably altered by treatment with relatively concentrated caustic alkali.

2. In the case of fullers' earth "activated" by contact with autolyzed yeast filtrate, aqueous alkali modified the physiological action in respect to its power to maintain the weight of pigeons on a deficient diet, but did not sensibly affect its antineuritic function.

3. By alkaline extraction of "activated" fullers' earth a crystalline antineuritic substance was obtained, the physiological action of which was apparently not due to adhering mother liquor.

4. On attempting to purify this substance further by recrystallization, its antineuritic properties were lost and the resulting product was found to be identical with adenine.

5. By suitable treatment of the resulting adenine, it acquired antineuritic properties, and the power to give a blue color with the *Folin-Macallum reagent*.

6. The explanation of the results obtained appears to be that an isomer of adenine is the chemical entity responsible for the characteristic physiological properties of the "vitamine" under investigation.

7. A hypothesis regarding the chemical nature of "vitamines" is suggested.

CHART I. Feeding Experiment 1 (Birds S 128, 137, and 140). Showing the effect of autolyzed yeast filtrate which was previously treated with alkali.

Feeding Experiment 2 (Birds S 130, 131, and 148). Showing the effect of autolyzed yeast filtrate freshly treated with alkali.

CHART II. Feeding Experiment 3 (Birds S 149 and 150). Showing the effect of "activated" fullers' earth which had been digested with alkali for 5 hours.

Feeding Experiment 4 (Birds S 153 and 154). Showing the effect of "activated" fullers' earth which had been digested with alkali for 10 minutes.

Feeding Experiment 5 (Birds S 155 and 156). Showing the effect of the filtrate from the earth used in the previous experiment.

CHART III. Feeding Experiment 6 (Birds S 151 and 152). Showing the effect of a neutralized alkaline extract of "activated" fullers' earth.

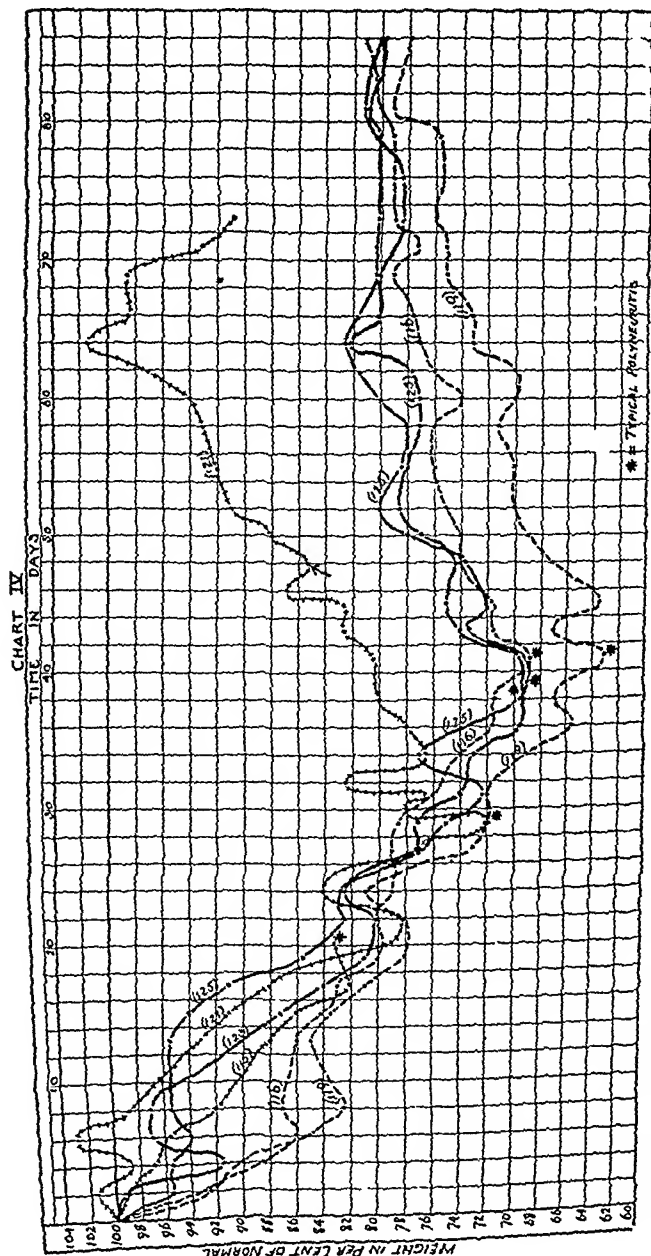

CHART IV. Feeding Experiment 7. Birds S 115 and 121 were retained as controls, S 116 and 119 received 4 mg. doses (119 increased to 10 mg doses after the 25th day), and 123 and 125, 2 mg doses of crystalline substance, melting point 315° , until the development of typical polyneuropitis. After becoming polyneuropitic all the birds except 115 received 10 mg. doses of the most crystalline needles (Fig 1) In the case of 121 the dose was increased to 50 mg at the point shown by the arrow

CHART V. Feeding Experiment 8. Bird 146 received 10 mg. and 147, 5 mg. doses of the moist crystalline needles (Fig. 1).

FIG. 1.

FURTHER STUDIES OF THE RELATION OF THE QUALITY OF PROTEINS TO MILK PRODUCTION,*

BY E. B. HART AND G. C. HUMPHREY.

WITH THE COOPERATION OF A. A. SCHAAL.

(From the Departments of Agricultural Chemistry and Animal Husbandry of the University of Wisconsin, Madison.)

(Received for publication, July 5, 1916.)

In an earlier publication¹ it was pointed out that the protein synthetic power of the mammary gland was not so distinct as to make it independent of the quality of the nitrogenous units furnished by the ration. It was shown by the final method of experimentation and calculation used that the proteins of the corn or wheat grain had a much lower efficiency for milk protein construction than the proteins of milk itself.

It was apparent from this work that the nutritive ratio or the plane of protein intake for milk production need not be a set ratio, dependent alone upon the quantity and quality of the milk produced, but could be varied, dependent upon the quality of the proteins in the ration. This harmonizes perfectly with the available facts concerning the relation of proteins to growth and does not give to the specialized group of cells constituting the mammary gland a synthetic power for proteins wholly independent of the quality of the amino-acids furnished by the blood stream.

It was further shown that the inefficiency of the proteins in a ration for milk production was concealed, at least for a comparatively short period, by the ability of the animal to metabolize its tissue proteins, thereby compensating for the deficiencies in the structure of the proteins of the ration and at the same time allowing a maintenance of milk secretion at a fairly high level. This phase of protein metabolism was made manifest by an in-

¹ Hart, E. B., and Humphrey, G. C., *J. Biol. Chem.*, 1915, xxi, 239.

creasing or decreasing nitrogen loss as the proteins ingested were either structurally inferior or superior. Further, it appeared possible that normally milk protein production was at the expense of body tissue and that the ingested proteins of a ration were utilized in restoration of catabolized tissue, thereby making their utilization analogous to the growth requirement. We pointed out that the proteins investigated showed a higher efficiency for milk production or restoration of utilized tissue than during growth alone. This was explained on the assumption that the catabolized tissue so supplemented the amino-acids originating from the ingested proteins as to raise their real efficiency—a condition arising because of the negative nitrogen balance of the animal. In the light of the modern theory of protein metabolism it would be unnecessary to assume that milk protein production was at the expense of body tissue, but rather that it was sustained directly by the amino-acids arising from the proteins of the ration.

After recognizing this inequality of proteins for milk production it was apparent that further studies, because of theoretical interest and practical importance, should be made of the efficiency for milk production of the common protein concentrates used in feeding milking animals. During the past year we have studied the utilization of the proteins of gluten feed, distiller's grains, oil meal, casein, and skim milk powder. Gluten feed represents the proteins from the endosperm of the corn kernel and what is included in the outer bran layers. *The embryo is not present*; this is an important distinction to be kept in mind. Distiller's grains may be derived wholly from the corn grain, but contain the embryo and its proteins. Some brands of distiller's grains may contain, besides corn, a small proportion of barley and rye. The brand used in this work was known as "Ajax" and we were assured that it was derived wholly from the corn kernel. The oil meal used was common "Old Process Meal," the residue from the flaxseed after expressing the oil by heat and pressure. The milk products were the common stock products of the market.

Plan of Experiment.

The plan of experimentation was to use a basal ration consisting of corn stover, silage, corn meal, and starch, to which would

be added the concentrates. The basal ration was maintained constant in relation to its source and proportion of nutrients for any individual in the different periods, the only variable in succeeding periods being the concentrate and starch. These were supplied in such quantities as to make the plane of protein intake and net available energy uniform in the several periods. As illustrative of the proportions of the various food materials in the ration when an animal was receiving daily approximately 50 pounds of material the following table is appended.

TABLE I.
Source and Proportion of Nutrients Used.

Three pure-bred Holsteins of large milking capacity were used for the work. Under normal herd management these animals produced from 45 to 55 pounds of milk daily. They were not with calf. The animals were maintained in a comfortable place and all excreta quantitatively collected. They were milked twice daily and exercised two to three times a week. Weights were taken weekly. The plan was to place each individual on any one of the rations for a 4 week period with immediate change to another concentrate, thus involving each animal in 16 to 20 weeks of observation. Preliminary to making the first records there was a feeding period of 1 week.

The urine and feces were analyzed daily for nitrogen, while a weekly analysis was made of a 7 day composite of milk. Our earlier observations had shown that with the nutrients from the corn grain, gluten feed, and corn stover, and a daily production of about 20 pounds of milk of average composition, the nitrogen

460 Quality of Proteins for Milk Production

equilibrium could not be maintained with a nutritive ratio of 1:8, equivalent to a plane of digestible protein intake of approximately 7 per cent, or of a total protein content of from 9 to 10 per cent of the ration. Nitrogen equilibrium could, however, be maintained even with somewhat higher production when the proteins were derived from skim milk. For these reasons it was planned to use rations with a nutritive ratio of approximately 1:8, as it was essential that the animals be in negative nitrogen balance or just in equilibrium in studies of this character. With an excess of nitrogen and the animal in positive balance relative efficiency of proteins for milk production cannot be determined.

The composition of the rations used is shown in Table II.

The rations were approximately identical in content of total protein and therms. The net energy available conformed closely to Armsby's standard of 7 therms for maintenance and 0.3 therm for each pound of milk produced by a 1,000 pound cow. These animals had an initial weight of 1,090, 1,085, and 1,120 pounds respectively, and produced daily about 40 pounds of milk. The rations contained approximately 2 pounds of digestible proteins, 50 per cent of which came from the particular concentrate under investigation.

only absorbed nitrogen is considered. For example, Animal 2 during the 3 weeks on gluten feed absorbed 1,974 gm. of nitrogen and excreted 1,040 gm. in the urine, while during a like period on oil meal it absorbed 2,187 and excreted 865 gm. and on distiller's

grains absorbed 1,964 gm. and excreted 716 gm. The absorbed nitrogen was not being used as efficiently during the gluten feed periods as it was during the periods of the other concentrates.

There was much less difference between the utilization of the proteins of oil meal and distiller's grains than between gluten

feed and oil meal or distiller's grains. Since the distiller's grains were derived from corn and include the embryo it is necessary to attribute to the proteins of the embryo of this grain a high efficiency. It was surprising to note how close an approach to nitrogen maintenance could be made with oil meal or distiller's grains and yet keep the nutritive ratio 1:8. While this ration did not accomplish this, yet the milk powder ration used in the same ratio did. We are not contending that the widest nutritive ratio compatible with nitrogen equilibrium subserves the best physiological status of these producing animals, but our data do show a large inequality in protein concentrates for the nitrogen maintenance of milking animals. Whether that quantity of proteins just sufficient for maintenance and milk production is the physiological quantity, or whether a liberal excess with its specific dynamic properties meets the needs best, involves again the much discussed but unsettled question of protein minimum.

Conforming with our earlier studies, these data again reveal the marked effect of the forces of maternity in maintaining milk production at a very high level and for a very long time although the animals were in negative nitrogen balance for practically 16 weeks. Their initial live weights were 1,090, 1,085, and 1,120 pounds respectively, while their weights at the time of terminating the experiment were 1,023, 1,008, and 1,038 pounds. Live weight had not greatly decreased, although the animals plainly showed emaciation and partial depletion of muscular tissue.

It should be made clear, however, that there was a gradual falling off in the total quantity of protein elaborated in the milk, as well as a slight lowering in the solids not fat and in the fat, as the negative nitrogen balance continued. The volume of milk also shrank slightly after prolonged negative balance, but yet was remarkably sustained for a period of 2 months.

To show these effects the composition and volume of the milk secreted by the several animals at different periods of observation are given in Table VI.

Efficiency of Concentrates Compared.

Any attempt to compare the efficiency of these protein concentrates for milk production must not only involve the quantity of protein secreted in the milk, but also the quantity of protein catabolized or stored during the periods of observation. On a negative nitrogen balance the supplementing effect of catabolizing tissue will probably raise the efficiency above its real value and thereby make a given concentrate appear of greater worth for milk production than for growth. This is inherent in the method of calculation and experimentation and we recognize the error introduced.

For purposes of making definite comparisons, however, we have calculated the percentage of efficiency for the various materials used on the basis of absorbed nitrogen, tissue anabolized or catabolized, and milk proteins produced. Manifestly the absorbed nitrogen should be used in the calculation rather than the total nitrogen ingested. In Table VII these comparisons are shown.

The average percentage of efficiency with the three animals was, on gluten feed 45, oil meal 61, distiller's grains 60, casein 59, and for the single individual on milk powder 60. There was a close and constant agreement among the different individuals receiving the same ration. With the rations used, gluten feed showed a comparatively low efficiency. The other materials ranged about 15 per cent higher and were in close agreement with each other. Chart 4 illustrates these differences and includes the data collected last year for the proteins of the wheat grain (wheat meal and wheat gluten), corn grain (corn meal and gluten feed), and

CHART 4. This chart illustrates the comparative efficiency for milk production of the proteins from the concentrates indicated. In 1915 the corn ration derived its concentrate from gluten feed and the wheat ration from wheat gluten.

milk powder supplementing corn stover. It should, of course, be borne in mind that the efficiency of a protein mixture will depend upon the source and proportion of the feeds constituting that mixture. For that reason permanently fixed percentages will probably be impossible for any concentrate. Their efficiency in any other mixture may be in the order determined by these experiments, but that can only be known definitely when more experiments are available. For example, gluten feed may or may not have the same percentage efficiency when clover hay forms the roughage. Attention should be called to the very high percent-

age of utilization in this mixture of the proteins of oil meal and distiller's grains and their favorable comparison with casein and skim milk powder, which is taken as representing the maximum attainable. This high efficiency is partly due no doubt to the additional supplementing they received from the catabolizing tissue of the animal, made necessary by a negative nitrogen balance, and would account for the higher utilization such a mixture showed when compared with the utilization during growth. For example, Professor McCollum² has found that on a mixture of 75 per cent of corn proteins and 25 per cent of oil meal proteins a pig will show a retention of approximately 40 per cent of the nitrogen of the ration, while 60 to 65 per cent of milk protein nitrogen will be retained on the same level of protein feeding; yet it should be clear that these proteins of oil meal and distiller's grains are superior, in the mixture used, to those from gluten feed, which likewise had available the supplementing amino-acids of catabolizing tissue.

SUMMARY.

Data are presented on the comparative value for milk production of the proteins of gluten feed, oil meal, distiller's grains, casein, and skim milk powder.

These concentrates furnished 50 per cent of the total digestible proteins of the ration and were used to supplement a basal ration of corn stover, corn silage, and corn meal. The total protein intake constituted about 10 per cent of the dry matter of the ration and the nutritive ratio was approximately 1:8.

With a daily production of 40 to 45 pounds of milk carrying 10 to 12 per cent of total solids, negative nitrogen balance persisted throughout the experiment of 16 weeks' duration. Only during the period of skim milk powder feeding was one of the animals storing nitrogen. In spite of this long negative balance milk secretion continued at the expense of catabolizing tissue. The total yield and total solids of the milk declined slightly after 2 months of continuous negative nitrogen balance.

There was a marked difference in the utilization of the concentrates; gluten feed showed a percentage efficiency of 45, oil meal

² Unpublished data from this laboratory.

61, distiller's grains 60, casein 59, and skim milk powder 60. These data represent the efficiency in the mixture used.

Possible errors in calculation may arise from the supplementing effect of the catabolizing tissue, thereby raising the figures above their true value, but nevertheless they do have comparative worth. Other roughages will be used in a further study of this problem.

These studies furnish additional evidence that the nutritive ratio or plane of protein intake for milk production may vary according to the nature of the concentrates and basal ration used.

NITROGEN DETERMINATIONS BY DIRECT NESSLERIZATION.

INTRODUCTION.

When the investigations on the colorimetric method for the determination of nitrogen were begun in this laboratory some years ago it was hoped that it would be possible to Nesslerize directly the ammonia produced by the destructive digestion of the urine with sulfuric acid and catalyzers.¹ No satisfactory solution of this problem was found, and aeration, which had proved so useful in Folin's method for the determination of ammonia in urine, was adopted for the preliminary removal of the ammonia from the digestion mixtures.

The removal of the ammonia as a feature of the method was only tentatively adopted, and we have never entirely given up

¹ Folin, O., and Farmer, C. J., *J. Biol. Chem.*, 1912, xi, 493.

the hope of finding a practical way of eliminating this step. In the meantime others have made attempts to solve this problem. Gulick,² Bock and Benedict,³ and Taylor⁴ have described procedures for directly Nesslerizing the digestion mixtures. The chief obstacle in the way of direct Nesslerization is, however, the presence of large amounts of sulfates, which leads to precipitation of the colored mercury ammonium compound used for the color comparison. Folin and Farmer adopted sulfuric acid and potassium sulfate for the destructive digestion of the urine, but did so only after they had decided to give up the direct Nesslerization of the digestion mixture. The other authors named above have made use of essentially the same digestion mixture as Folin and Farmer, and have therefore been working under the least favorable conditions from the standpoint of direct Nesslerization. We have now attacked the problem in another way and believe that we have found an almost ideal method for the colorimetric estimation of total nitrogen in urine by direct Nesslerization of the digestion mixtures.

The Destructive Digestion of Urine.

The starting point of our investigation was the discovery that phosphates interfere very little, if at all, certainly much less than sulfates, with the Nesslerization of ammonia. This discovery virtually solved the problem, for it has long been known that mixtures of sulfuric acid and phosphoric acid are very effective in connection with destructive digestions of nitrogenous materials. The proportion of phosphoric acid heretofore used for the purpose is, however, rather small (one part of phosphoric anhydride to five of sulfuric acid) in comparison with the proportions which we wished to use and can use in micro digestions. In ordinary long macro digestions the usefulness of phosphoric acid as an accessory catalyzer is limited by the fact that at very high temperatures the digestion flasks are speedily and completely corroded by the non-volatile phosphoric acid. Even pure silica ware is attacked above 400° C. by phosphoric acid.

² Gulick, A., *J. Biol. Chem.*, 1914, xviii, 541.

³ Bock, J. C., and Benedict, S. R., *J. Biol. Chem.*, 1915, xx, 52.

⁴ Taylor, A. E., and Hulton, F., *J. Biol. Chem.*, 1915, xxii, 63.

The rapid etching of the glass by phosphoric acid is by no means avoided even in our micro digestion, and this somewhat unfortunate feature we have had to accept. This drawback is, however, a small one in comparison with the many advantages gained. We employ ordinary phosphoric acid "syrup" (containing about 83 per cent H_3PO_4), and have tried various proportions between five volumes of phosphoric acid to one of sulfuric acid and one of phosphoric acid to two of sulfuric acid. In each case we use 1 cc. of the acid mixture for the digestion, so that the amount of sulfuric acid used has varied between two-thirds and one-sixth of 1 cc.

The larger the proportion of phosphoric acid the more rapid is the digestion (in the absence of other catalyzers) and the easier is it to Nesslerize the ammonia produced without getting turbidity. But the larger the proportion of phosphoric acid the more rapid is the action on glass. The silica thus liberated forms a heavy, *conspicuous sediment in the digestion mixture*. This sediment does not interfere with the Nesslerization of the ammonia, but it must be removed before the color comparison is made. We remove it by help of a centrifuge from a small portion of the Nesslerized solution. It can also be removed by filtering through small plugs of cotton, but not through paper, because paper absorbs a part of the coloring matter. Because of the formation of silica from the glass we usually prefer to use test-tubes of silica. The phosphoric-sulfuric acid mixtures mentioned attack silica test-tubes to such a slight degree that unless the digestion is *continued unnecessarily long, clear solutions are obtained from the digestion mixtures and one operation, namely the removal of the silica, is saved*. The chief drawback to the use of silica tubes is their initial cost, though they seem to last indefinitely, except for mechanical breakage. Also the heavy "semitransparent" tubes which we use are rather opaque so that the progress of the digestion is less readily observed than when glass tubes are used. The light foam formed during the early stages of the digestion can scarcely be seen through these tubes, and careful watching is necessary to keep the contents from foaming out of the tube.

Hard glass test-tubes of rather large size (200 mm. \times 13 to 15) are preferable to small ones. These tubes will last longer if

the bottom is somewhat thickened by heating over a hot flame. This operation does not take more than 2 or 3 minutes, and the pear-shaped bottom of the tubes obtained is rather an advantage because of the small total volume of the digestive mixture. It is, however, not at all essential that the form of the test-tubes be thus altered.

In the course of our endeavors to determine which acid mixture, if any, is the most suitable for use with glass tubes we have found that a little copper sulfate added as an accessory catalyzer greatly accelerates the speed of the digestion and thereby also reduces the corroding action on the glass tubes. The catalytic effect of the copper on the destructive digestion is not equally striking with all mixtures of phosphoric and sulfuric acid. With the mixture 5:1 the digestion is scarcely, if at all, hastened by the addition of copper.

The following protocol may be cited to indicate the course of the destructive digestion on urine. A sample of urine of rather more than average resistance was diluted so that 1 cc. contained 1.5 mg. nitrogen. Two small drops ($\frac{1}{16}$ cc.) of 10 per cent copper sulfate were used in each digestion, and the digestions were as nearly similar with respect to heat as possible. The digestion time was counted from the first appearance of white sulfuric acid fumes in the tubes.

H ₃ PO ₄	H ₂ SO ₄	Digestion time.
		<i>min.</i>
0	1	30
1	2	25
1	1	9
2	1	2.5
3	1	2.5
5	1	3

From the results noted above it would seem that a mixture containing two or three volumes of phosphoric acid to one of sulfuric acid is most suitable for the destructive digestion of urine. Since the action on the glass in each case is small, and since phosphates are to be preferred to sulfates from the standpoint of Nesslerization, the mixture having the higher proportion of phosphoric acid (3:1) is on the whole to be preferred.

The use of copper sulfate as a catalyzer in digestion mixtures which are to be Nesslerized may seem a doubtful expedient. So long as we worked with silica test-tubes there was no need for any accessory catalyzer and we did not try the effect of copper; but, in connection with test-tubes of glass, it did seem important to reduce the corrosion by shortening the digestion period, and it was thought that the added copper would be removed as copper phosphate together with the silica during the centrifuging process. In the presence of phosphates, however, copper in small amounts is dissolved by sodic hydrate so that the presence of the copper does not interfere with the final Nesslerization of the digestion mixtures. This valuable accessory catalyzer can therefore be used, and is added to the standard as well as to the digestion mixtures.

As to the amount of copper sulfate needed, we find that $\frac{1}{15}$ of 1 cc. of a 10 per cent solution is enough (*i.e.*, two drops from a 1 cc. pipette which delivers 29 to 30 drops when emptied). It is a curious fact that the difference between the effect on the digestion of one such small drop and two drops of copper sulfate is almost as great as that between one drop and none. With one drop the digestion time with one highly resistant urine was about 10 minutes; with two drops it sank to less than 3 minutes (with the acid mixture 3:1).

The final color of the digestion mixture when copper sulfate is added in the proportions indicated is sometimes a light straw yellow or green instead of blue, particularly in the case of urines containing much carbonaceous matter. A similar phenomenon is obtained when "too much copper" is used in connection with ordinary macro Kjeldahl digestions. The current view that copper sulfate functions as a self-regenerating catalyzer in relation to the oxidations accompanying the Kjeldahl digestion is rather negatived by this phenomenon, for if such self-regeneration occurred, the original blue color of cupric sulfate should come back toward the end of the digestion, or at least upon adding water. This does not happen. If our interpretation is correct, it would explain why two drops of copper sulfate proved so much more effective than one drop in the experiment recorded above. The one drop may not have yielded enough oxygen for the organic matter present, and the remainder had therefore to be oxidized

by the sulfuric acid alone. We have tried other catalyzers besides copper sulfate, but have come to the conclusion that copper sulfate is probably, on the whole, the most serviceable. Ferric chloride is fully as effective as copper sulfate; salts of cadmium, uranium, and manganese are about as good; mercury is better. But from the standpoint of the subsequent Nesslerization we have found these catalyzers to be less desirable than the copper sulfate.

Nothing is gained by a too speedy oxidation of the carbonaceous materials because there is no evidence showing that the hydrolytic removal of nitrogen as ammonia is equally accelerated and the digestion must anyhow be continued for at least 2 minutes.

Nessler's Reagent.

In almost every text-book describing Nessler's reagent is found the somewhat discouraging statement that the solution "improves with age;" that is, the older the reagent, up to one or more years, the more likely it is to give crystal-clear solutions instead of turbid ones, when added to ammonia. We are inclined to believe that in so far as any such improvement does occur it is due to a reduction of the alkalinity of the solutions by virtue of a gradual absorption of carbon dioxide from the air. For we have satisfied ourselves that the chief, if not the only, cause of the turbidity is the excessive alkali content of the reagent (usually 20 per cent caustic potash). The presence of free hydroxide in amount almost equal to that added with Nessler's reagent is necessary for the development of a deep color with ammonia, but a slightly excessive concentration of alkali at once precipitates the colloidal colored ammonia compound. When the Nessler reagent is added to the ammonium solution, local zones of excessive alkalinity occur and coagulate a part of the solution. With experience and dexterity in the mixing of the two solutions the cloudiness can be diminished, and sometimes entirely prevented, except when the amount of ammonia present is large (more than 1 mg. of ammonia nitrogen per 100 cc. of solution). The reason for the remarkable improvement in the efficiency of Nessler's reagent which Folin and Farmer obtained by diluting it with several volumes of water immediately before adding it

to the ammonia solutions is therefore clear. The preliminary dilution prevents the presence of excessive alkalinity in any part of the mixture.

Since a certain considerable concentration of alkali is necessary for the development of the color in the Nesslerization process and since even a momentary excessive concentration of alkali in any part of the Nesslerized mixture ruins the determination, the practice of adding all the needed alkali in the form of undiluted Nessler's reagent is manifestly faulty. The preliminary dilution of the reagent has one drawback; unless the reagent is added almost immediately (within a few minutes) the diluted reagent decomposes and becomes unfit for use. Because of these flaws in the Nesslerization process we have made some radical changes in the formula for the preparation of the reagent.

Aside from its excessive alkali concentration Nessler's reagent contains too little potassium iodide. It is quite true that too much potassium iodide destroys the value of the reagent so that it gives little or no color with ammonia, and this fact is evidently the reason why the minimum amount of potassium iodide capable of holding the mercuric iodide in solution came to be adopted. There is a very wide margin, however, between the minimum amount and the amount which materially lessens the efficiency of the solution.

Mercuric potassium iodide, $\text{HgI}_2\cdot 2\text{KI}$, is a definite commercial product the aqueous solutions of which can be diluted to a concentration of 5 or 6 per cent before it begins to decompose and set free the insoluble mercuric iodide. A solution of this neutral salt gives good Nesslerization results when added to ammonia solutions containing sodium or potassium hydroxide. Much better results are, however, obtained when a part of the needed alkali is present in the double iodide solution.

The preparation of this mercuric potassium iodide solution is very much easier than the preparation of ordinary Nessler's reagent, and the solution makes an excellent stock solution for Nessler's reagents of any desired degree of alkalinity. To prepare the double iodide solution dissolve approximately 75 gm. of potassium iodide in 50 cc. of warm water, add 100 gm. of mercuric iodide, and stir.

The solution is complete in a few minutes, but probably be-

cause of impurities in the mercuric iodide it is usually not perfectly clear. Dilute with water (400 to 500 cc.), filter, and make the filtrate up to a volume of 1 liter.

For the direct Nesslerization of the digestion mixtures with which we are dealing in the present paper, we prefer a Nessler reagent containing about 2 per cent of sodium hydroxide. To 300 cc. of the double iodide solution add 200 cc. of 10 per cent sodium hydroxide, 500 cc. of water, and mix. 15 cc. of this modified Nessler reagent rapidly added from a measuring cylinder will yield crystal-clear mixtures with as large amounts of ammonia as are involved in our colorimetric nitrogen determinations (0.7 to 1.6 mg. ammonia nitrogen).

It will be noted that sodium hydroxide, instead of potassium hydroxide, is used in the preparation of our Nessler's reagent. Potassium hydroxide is doubtless equally good for the purpose, but it is no better and is more expensive. A faultless 10 per cent caustic soda for Nessler's reagent can be prepared as follows from the technical caustic soda used in Kjeldahl distillations:

Prepare a 45 per cent caustic soda solution by the addition of 10 pounds (4.5 kilos) of the caustic soda powder to 7 liters of water, and let stand for 2 or 3 days in order to let the carbonate and sulfate settle out. Dilute the clear supernatant solution to the desired concentration (10 per cent). Let stand for 24 hours and filter from the oxides of iron; or let the solution stand in well closed bottles for several days and remove the clear supernatant solution by means of a siphon.

Neutralization of the Digestion Mixture.

The depth of color which Nessler's reagent produces with a given amount of ammonia depends, as already indicated, to a very large extent on the degree of alkalinity prevailing in the mixture. Free hydroxide is necessary to produce any color at all in the solution, and the more hydroxide is present the deeper becomes the color. The concentration of free alkali permissible is, on the other hand, rather sharply limited by the formation of turbid or "smoky" instead of crystal-clear solutions. The amount of alkali required to neutralize the acid digestion mixture and to give a suitable degree of alkalinity must therefore be determined with some care and, of course, must be substantially the same as that in the ammonia solution which is to be used as a standard. Proper attention to this detail is absolutely

essential for correct results. The free alkali in the unknown urine digestion mixture and the standard should agree to within 0.5 cc. of 10 per cent sodic hydrate.

For reasons which will be given later it is better when working with urine to dilute the final Nesslerized solution to 200 cc. instead of to 100 cc., as is done in the original method. In this volume (200 cc.) there should be 2 or 3 cc. of free 10 per cent sodic hydrate in addition to the alkali added in the form of our Nessler reagent. It is possible to secure perfectly clear solutions when as much as 6 or 7 cc. of alkali has been added, but the danger of getting "smoky" mixtures is then so great and the increase in color due to such larger concentration of alkali is so small that it is much better to use the smaller excess of alkali indicated. To secure this excess of alkali with a sufficient degree of uniformity is not particularly difficult, but there are several factors to be taken into account. The phosphoric-sulfuric acid mixture is slightly viscous; unless it is measured out in a reasonably uniform manner (*i.e.*, as to the length of time the delivery pipette is allowed to drain) the variations in the amount of acid present may be considerable. The amount of acid so delivered must be titrated with the alkali, and with phenolphthalein as indicator, and due account must be taken of the fact that one-third of the base-absorbing power of the phosphoric acid is not included in the titration value. For example, 1 cc. of our phosphoric-sulfuric acid mixture (5:1) required from 12.6 to 12.8 cc. of 10 per cent sodic hydrate to yield a faint yet unmistakable pink color with the phenolphthalein. Since about five-sixths of this acidity (or 10.6 cc.) was due to the phosphoric acid, $12.7 \div 5.3$ cc. or 18 cc. were required for the neutralization of the acid. To get a surplus of 2 cc. of 10 per cent alkali required therefore the addition of 20 cc. of the 10 per cent sodic hydrate. A certain amount of sulfuric acid is lost during the digestion. This loss is slightly larger when working with (15 cm.) silica test-tubes than when hard glass test-tubes (190 mm. \times 15 mm.) were employed. In the latter case the appearance of the sulfuric acid fumes becomes unmistakable before the fumes begin to escape at the top and it is accordingly much easier to regulate the flame so as to reduce the loss of acid fumes. The losses incurred are equivalent to from 0.1 to 0.3 cc. 10 per cent sodic hydrate and are negligible.

482 Nitrogen Determinations by Nesslerization. I

In this connection it may be noted that the destructive digestion of the urine is conducted in test-tubes the mouths of which are closed with watch-glasses as soon as the white sulfuric acid fumes make their appearance. While this is done primarily to prevent the loss of acid the analytical process is thereby further simplified since hoods or fume absorbers are no longer needed.

In thus virtually eliminating the loss of sulfuric acid fumes we are also eliminating all danger of losing ammonia together with those fumes. We are convinced that this danger is a real one, that both in macro and in micro Kjeldahl digestions with sulfuric acid losses of ammonia do occur because of excessive or unduly prolonged digestions. We have often encountered such losses in the difficult micro digestions involved in determining the non-protein nitrogen of blood and have met with similar losses in ordinary Kjeldahl digestions of urine. The practice, still fairly common, of digesting urine for 2½ to 3 hours with sulfuric acid plus 20 gm. of potassium sulfate and catalyzer not infrequently yields less ammonia than is obtained by 45 minutes' digestion with 5 gm. potassium sulfate together with sulfuric acid and catalyzer.

The following practical working formulas for the neutralization of the acid and for securing proper alkalinity for the Nesslerization may prove useful.

H ₃ PO ₄	H ₂ SO ₄	10 per cent alkali required.
5	1	17/12 of the titrating value + 2 cc.
3	1	11/8 " " " " + 2 "
2	1	4/3 " " " " + 2 "
1	1	5/4 " " " " + 2 "

In the above formulas concentrated sulfuric acid and the concentrated (83 per cent) phosphoric acid are assumed to have, volume for volume, equal titrating values. This is not strictly correct; 29 cc. of our sulfuric acid had the same titrating value as 33 cc. of the phosphoric acid; but the discrepancy is immaterial.

The concentrated phosphoric acid used with sulfuric acid for the destructive digestion of urine contains only one somewhat disturbing impurity, namely calcium. Practically all of this calcium is, however, precipitated as sulfate when the phosphoric acid is mixed with concentrated sulfuric acid. The mixed acids

are allowed to stand over night, and the mixture is then filtered through an asbestos mat on a Buchner funnel. The asbestos mat is kept in place for this filtration by a layer of pebbles.

Dilution of the Digestion Mixture.

By our Nesslerization process ammonia equivalent to 1 mg. of nitrogen can be Nesslerized in a volume of 100 cc., notwithstanding the large amounts of salts formed by neutralization of the digestion mixture. The whole operation becomes easier if 200 or 250 cc. flasks are used. The rinsing of the digestion mixture into the flask is easier because one can use more water. Because of the larger volume of water, the heat developed on adding the alkali produces very little rise in temperature (only 5-7°C.) and it is hardly necessary to cool the mixtures before Nesslerizing. The chief reason why we prefer the larger volumetric flasks is, however, that with these larger volumes as much as 2 or 3 mg. of ammonia nitrogen will give just as perfect Nesslerizations as 1 mg.; and it often happens that 1 cc. of diluted urine does give as much as 1.5 or 1.6 mg. of nitrogen.

Standard Ammonium Sulfate Solution.

Kahlbaum's ammonium sulfate, labelled c.p. for analysis, is pure and can be used in the preparation of standard ammonium sulfate solution. It must be dried, however, either by being kept in a desiccator over sulfuric acid for a day or two, or by heating at about 110°C. for an hour before being weighed out.

Pure ammonium sulfate can be prepared from ordinary sulfate by decomposing it with strong sodic hydrate and aspirating the liberated ammonia into sulfuric acid. The ammonium sulfate solution so obtained is precipitated by the addition of alcohol, and is then recrystallized two or three times by solution in water followed by alcohol precipitation. After the alcohol has evaporated from the last precipitate it is dried in a desiccator. 4.716 gm. of this salt per liter gives a stock solution containing 1 mg. per cc. To keep out moulds the solution should also be a 0.2 N solution of sulfuric acid. 20 cc. of our solution prepared from a sulfate, made as indicated above, gave by distillation and titration 20.006 mg. N. Ordinary ammonium sulfate cannot

be used either on the basis of direct weight or on the basis of "ammonia" determinations made by distillation and titration, because it contains pyridine bases which distill and titrate like ammonia yet do not react with Nessler's reagent.

From the stock solution of standard ammonium sulfate we prepare by appropriate dilution with water a weaker working solution containing 1 mg. of nitrogen per 20 cc. This degree of dilution is advantageous because the same solution can also be used in connection with blood analysis, when a standard of 0.25 or 0.5 mg. of nitrogen is more often used than 1 mg.

The Use of Ostwald Pipettes.

The modified Ostwald 1 cc. pipettes with which the diluted urine is measured should, of course, be calibrated. It is perhaps not superfluous to state that these pipettes are drained against the sides of the test-tube for 10 seconds and are then blown clean, while dragging the pipette against the sides of the tube. Under ordinary laboratory conditions the weight of distilled water which the pipettes should deliver in order to represent 1 full cc. is 997 mg.

The Use of the Colorimeter.

The unavoidable uncertainty inherent in all light color comparisons is of course considerably greater than the uncertainty involved in titrations of the ammonia obtained in the ordinary Kjeldahl method. By proper attention to certain minor details in the use of the colorimeter the error involved need never exceed 1 per cent, and the average results as well as a great many individual determinations can become practically perfect. A number of points and suggestions bearing on the use of the Duboscq colorimeter have gradually accumulated in this laboratory and some of these may prove helpful to others.

(a) It should be obvious that the zero points on the scales of the colorimeter should not be accepted as true zero points without verification. Long has recently called attention to this point. The Duboscq colorimeters, as a matter of fact, are very seldom accurate with reference to the zero points. We have an instrument which is accurate, but it has been obtained by selec-

tion of suitable cups from among the large number of cups available in this department.

(b) Another obvious point is that the optical parts of the instrument should be freed from dust. Hardly a single black speck should be visible in either field. There are three places on the lower part of the instrument which can advantageously be made dust-proof by being sealed up with microscope cover glasses (and Canada balsam or mucilage).

(c) Even perfectly clean instruments with mechanically correct zero points are not necessarily optically correct. One field seems darker than the other no matter how carefully the instrument is adjusted to the light. In many cases this inequality is due to the ageing of the Canada balsam with which the glass plate is sealed onto the top of the parallelopipeds inside the colorimeter. That plate serves no useful purpose, and we remove it by cautious soaking in a very shallow layer of xylol (so as not to remove the glass plate on the side as well).

(d) The apparent inequality of the two fields in the colorimeter is in part a physiological phenomenon, for with the same instrument one observer may find the right field and another the left field to be the darker when the two fields should be equal.

Additional essentials for accurate colorimetric readings are a comfortable position and a suitable environment. Most persons who do not use an artificial light use the colorimeter directly in front of, and near a window, and stand behind the scale side of the colorimeter when using it, thus facing the window. This is about the worst possible condition, unless the light comes only through an opening in a shade covering the window. The eye is far less sensitive to variations in light when one has just looked at a bright sky or other bright object out of doors. We are under the impression that it is easier to make the color comparison from the side of the instrument than from behind, and most persons will undoubtedly make better readings by sitting in a comfortable position than by standing; for fatigue is fatal to good colorimetric readings. By putting the instrument in the middle of the laboratory, *i.e.*, several feet away from the window, on a stool of about the same height as an ordinary chair, and sitting down (at one side of the instrument instead of behind), long series of colorimetric comparisons can be made without fatigue and consequent uncertainty.

In reading the unknown we never make more than one reading, and we take this reading after having got the eye adjusted to the appearance of the standard solution when both fields should look alike. Having adjusted the instrument and determined the appearance of the field, we make one or two readings of the standard. We then replace the standard in one cup by the unknown and take only one careful reading. When making a long series of color comparisons we reread the standard against itself after each two of the unknowns. We consider this an essential condition, for without thus readjusting the eye the appearance of equality will gradually shift either up or down.

Concise Description of the Colorimetric Nitrogen Determination (for Urine).

Solutions and Apparatus Required.—A Nessler reagent containing 5 to 6 per cent mercuric potassium iodide, $\text{HgI}_2 \cdot 2\text{KI}$, and 2 per cent sodic hydrate. A standard ammonium sulfate solution containing 1 mg. of nitrogen per 20 cc. An approximately 10 per cent sodic hydrate solution. A filtered mixture of one volume concentrated sulfuric acid (100 cc.) and three volumes concentrated (85 per cent) phosphoric acid (300 cc.), to which mixture has been added one-fifteenth volume (15 cc.) 10 per cent copper sulfate ($\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$) solution. A calibrated long stem 1 cc. Ostwald pipette. Hard glass test-tubes (preferably 190 mm. \times 15 mm.), volumetric flasks (capacity 100 cc. and 200 or 250 cc.), microburners, an ordinary 1 cc. pipette for measuring the phosphoric-sulfuric acid mixture. A high grade colorimeter (Dubosecq).

Dilute the urine so that 1 cc. contains from 0.7 to 1.5 mg. nitrogen. Urines having a specific gravity of 1.018 or less should be diluted to one in five. Urines having a specific gravity of 1.030 or over should be diluted to one in twenty. For urines having specific gravities between 1.018 and 1.030 a dilution of one in ten is appropriate.

With an Ostwald pipette measure into the test-tube 1 cc. of diluted urine. Add (with an ordinary pipette) 1 cc. of phosphoric-sulfuric acid and a fresh quartz pebble, or better, a piece of granite to prevent bumping.

Heat over a microburner, with the bottom of the test-tube within 1 cm. of the top of the burner, until nearly all the water has been driven off as indicated by the absence of foaming and by the appearance of the denser sulfuric acid fumes within the test-tube. This should occur in 2 to 5 minutes. Cover the mouth of the test-tube with a watch-glass and continue the heating with a flame so regulated that only a little of the acid fumes escape from the test-tube. In 0.5 to 3 minutes, counted from the time the test-tube was closed, the digestion should be clear and blue, green, or light straw yellow in color. This color is due to the copper. Continue the heating for another 30 to 60 seconds. (In no case should the total heating time be less than 2 minutes after the mouth of the test-tube has been closed).

Remove the flame and allow the test-tube to cool where it is for 2 minutes. Add water, and rinse the contents of the tube into a 200 or 250 cc. volumetric flask, using about 150 cc. of water for this purpose. Determine the titratable acid content of 1 cc. of the phosphoric-sulfuric acid mixture (as delivered by the 1 cc. pipette regularly used for measuring the acid). The titration is made with 10 per cent sodic hydrate and with phenolphthalein as indicator. Add to the diluted digestion mixture 10 per cent sodic hydrate in amount equal to $\frac{11}{8}$ times the titrating value obtained, plus 2 cc. for alkalinity. It is, of course, most convenient to dilute the alkali so that the required amount can be added with a pipette. Into another volumetric flask, of the same capacity as is used for the digestion mixture, introduce 1 cc. of the concentrated acid mixture and 20 cc. of the standard ammonium sulfate solution. Add about 125 cc. of water and then the same amount of sodic hydrate as in the case of the unknown. Mix well. Then add, with a cylinder, to each flask 15 cc. of our dilute Nessler's solution and mix quickly. Fill to the mark with water and mix. Pour out a part of the unknown (as an additional precaution against incomplete mixing), and centrifuge, or filter, through a small cotton plug, a portion of the remainder for the colorimetric comparison. If the sediment obtained is mixed with a red deposit the Nesslerization has not been successful and the determination must be discarded. The liquid above the sediment (or the filtrate) must be crystal-clear, not the least bit "smoky." Adjust the colorimeter, with the standard set

at 20 mm. in both cups, until the two fields are as nearly alike as it is possible to get them. Then make two or three color comparisons with the standard against itself, and when the result is accurate, replace the standard in one of the cups with the unknown, and make one leisurely, careful reading.

In a series of three or more simultaneous nitrogen determinations it is necessary to let every third color comparison be a comparison of the standard against itself.

Analytical Results.

From the following table of urine analyses, by Kjeldahl's method and by our colorimetric method, it will be seen that the differences between the two series of results are so small as to be of no practical significance. The majority of these determinations were made by the help of silica test-tubes, but many were made simultaneously in silica tubes and in glass test-tubes. The Nesslerized solutions obtained from the glass tubes were in some cases centrifuged, in others filtered through a little cotton, packed into the stem of a funnel. From the standpoint of accuracy one procedure is as good as another.

Nitrogen in Gm. per Liter of Urine.

NITROGEN DETERMINATIONS BY DIRECT NESSLERIZATION.

II. NON-PROTEIN NITROGEN IN BLOOD.

By OTTO FOLIN AND W. DENIS.

(From the Biochemical Laboratories of the Harvard Medical School and of the Massachusetts General Hospital, Boston.)

(Received for publication, July 27, 1916.)

In our original colorimetric method for the determination of non-protein nitrogen in blood the protein materials are precipitated with methyl alcohol and a little zinc chloride. This precipitation is not free from possible sources of error. Some nitrogenous lipoids may get into the alcoholic filtrate (Greenwald); and some nitrogenous materials, such as amino-acids, creatine, etc., which should go into the filtrate, may be held back in part by the protein precipitate. An additional drawback to this precipitation is the presence of ammonia in all but the best and most expensive grades of alcohol. The chief drawback to the use of alcohol as a precipitant in blood analysis is, however, the fact that it dissolves too much fat. The large amount of highly resistant carbonaceous material, which gets into the alcoholic filtrate in the form of fat, makes the subsequent destructive digestion of the residue, without loss of ammonium sulfate, a distinctly difficult process. If the alcohol is free from ammonia (or due allowance made for the alcoholic ammonia) and the oxidation is made with care, the non-protein nitrogen obtained represents substantially the correct value, but it is scarcely to be doubted that in the hands of careless or inexperienced workers the results obtained will often be low.

The difficulties arising from the presence of excessive amounts of carbon in the alcoholic filtrates are even more serious; in fact we consider them practically fatal when phosphoric acid is substituted for the greater part of the sulfuric acid in the destructive digestion of the blood filtrates. A smooth and rapid digestion

is well-nigh indispensable for a high degree of certainty in the values obtained by direct Nesslerization of the digestion mixtures. We have therefore reluctantly abandoned alcohol as a protein precipitant in connection with this determination and have endeavored to find some more serviceable reagent.

The number of blood precipitants capable of fulfilling the somewhat rigid requirements of this particular determination is not large, and for a time it looked rather doubtful as to whether a suitable reagent could be found. All reagents yielding much carbon, or nitrogen, or much acid, in the filtrate had to be discarded. All reagents involving heating are useless, because by heat (half an hour in a water bath) the nitrogen of normal blood filtrates may be increased to twice the real value.

In the course of our study of this problem it occurred to us that *m*-phosphoric acid might prove serviceable and peculiarly suitable. Since we are using phosphoric acid in large part for our destructive digestion, the presence of phosphates in the filtrates would be no disadvantage. In earlier times *m*-phosphoric acid was frequently used as a precipitant for proteins, but at the present time it is seldom employed, except in laboratory exercises for students and in technical processes. The *m*-phosphoric acid which we have tried is the common so called "glacial phosphoric acid" to which is ascribed the formula $\text{HPO}_3 \cdot \text{NaPO}_3$. The product is remarkably effective as a precipitant for the blood proteins. It is better than colloidal iron and fully as good as trichloroacetic acid for this purpose. It yields filtrates which are as colorless and clear as water, and which remain clear. These filtrates boil in test-tubes practically like water; *i.e.*, without foaming. The excess of *m*-phosphoric acid required for complete precipitation of the proteins is small; so small, in fact, that no allowance need be made for it in connection with the subsequent neutralization and Nesslerization of the digestion mixtures. The increase in the phosphoric acid content of those mixtures due to residual *m*-phosphoric acid is little if any more than equivalent to the loss of sulfuric acid fumes which occurs during the destructive digestion. The amount of carbon present is also insignificant. The complete digestion and oxidation of the residue is as speedy and complete as the destructive digestion of urine, the only difference being that 10 cc. of water, instead of

1 cc., must be boiled off before the destructive digestion begins. For the preparation of blood filtrates free from proteins and suitable for the determination of the non-protein nitrogen "glacial phosphoric acid" (*m*-phosphoric acid) is therefore better, according to our experience, than any other reagent heretofore used for this purpose.

In one particular glacial phosphoric acid falls short of being an ideal reagent for the preliminary removal of the blood proteins. *M*-phosphoric acids are not stable in the form of solutions. In solutions they gradually change to ordinary (*o*-) phosphates and thus lose their characteristic power of precipitating protein materials. This drawback to the use of glacial phosphoric acid solutions is not of much consequence, because the material is not expensive in comparison with the other blood precipitants employed. Adequate recognition of the fact that phosphate solutions of unknown age must not be used is, however, absolutely indispensable for reliable results. We have not found any definite information in the literature as to the speed with which the change of *m*-phosphoric acid into the *o*- compound takes place, except for the bare statement that the change is more rapid in dilute than in concentrated solutions and is greatly accelerated by heat.

Glacial phosphoric acid sticks dissolve somewhat slowly but completely in four parts of cold water. A stick weighing 20 to 25 gm. dissolves in the course of about half an hour when the mixture is shaken occasionally. 5 cc. of the 25 per cent solution so obtained are adequate for the precipitation of 10 cc. of blood. The solution if kept in a cool place will remain serviceable for 3 days. If needed for immediate use the reagent can be dissolved in hot water in the course of a few minutes; but solutions so made will not keep their precipitating power as long as the solutions made without heat.

The blood filtrates obtained with *m*-phosphoric acid solutions which have deteriorated beyond the permissible point may be perfectly water-clear so that it is not possible to tell by inspection at this stage whether the precipitation has been satisfactory; but such filtrates foam considerably in the test-tube when the surplus water is boiled off. Whenever such foaming is encountered the result obtained in the non-protein nitrogen determina-

tion must therefore be regarded with suspicion, particularly if the figures obtained are high.

The determination of the non-protein nitrogen is carried out as follows.

To about 20 cc. of water in a 50 cc. volumetric flask add 5 cc. of blood. Add 3 cc. of 25 per cent *m*-phosphoric acid and mix. Allow the mixture to stand for 1 to 24 hours, and fill up to the mark with water; mix thoroughly and filter through a dry filter paper. The first few drops of the filtrate are sometimes not water-clear and must then be put back on the filter or discarded. It is not essential that the mixture should be left standing for an hour as indicated. If desirable, the contents can be made up to volume at once. By then transferring the mixture to another flask, large enough to permit vigorous agitation, and shaking for 3 to 5 minutes, absolutely clear filtrates can be obtained immediately. On the other hand it makes no difference if the mixture is allowed to stand for 24 hours before it is diluted, mixed, and filtered.

Transfer 10 cc. of the filtrate (corresponding to 1 cc. of blood) to a hard glass test-tube (190 mm. \times 13 to 15 mm.); add a piece of crushed granite or quartz and 1 cc. of the acid mixture used for the destructive digestion of urine (100 cc. sulfuric acid, 300 cc. phosphoric acid, and 25 cc. 10 per cent copper sulfate solution).

Boil off the water over a microburner, or in a bath of saturated calcium chloride solution, and complete the digestion exactly as in the case of urine; *i.e.*, cover the mouth of the test-tube with a watch-glass as soon as white sulfuric acid fumes begin to appear and continue the heating for about half a minute after the visible carbonaceous materials have been oxidized. Let cool for 2 minutes, add water, and rinse the contents into a 100 cc. volumetric flask, using 60 to 70 cc. of water in all.

To neutralize the mixture add $\frac{1}{3}$ times the amount of 10 per cent sodic hydrate indicated by the titrating value of the phosphoric-sulfuric acid mixture, plus 1 cc. extra for alkalinity. Moderate variations in the degree of alkalinity are not nearly so important when working with normal blood, *i.e.*, with only about 0.3 mg. of ammonia nitrogen, as when working with 1 mg.

or more of nitrogen in urine analysis. A difference of 1 or 2 cc. of 10 per cent alkali makes scarcely any appreciable difference in the depth of the color produced. An excess of 2 or 3 cc. of alkali does somewhat alter the shade of color obtained (making it more greenish) and thus makes the color comparison somewhat more uncertain.

Cool the neutralized solution in running water, and add 10 cc. of the Nessler reagent, described in the preceding paper. Mix, centrifuge, or filter through cotton, from the suspended silica. If the destructive digestion is made in silica test-tubes the digestion mixtures are clear and no filtration is needed. Compare with standard Nesslerized ammonia solutions as in urine analysis.

The standard should usually consist of 0.5 mg. of ammonia nitrogen plus 1 cc. of the phosphoric-sulfuric acid mixture, diluted, neutralized, cooled, and Nesslerized as in the case of the unknown (in a 100 cc. volumetric flask).

In the analysis of blood unusually high in non-protein nitrogen a standard of 1 mg. of ammonia nitrogen may be needed. In working with such unknown blood we prepare the standard as follows: We dilute the acid, add the requisite alkali, and cool without adding the standard ammonia until we have seen the color developed in the unknown. By inspection one can then readily tell how strong a standard ought to be used. In the case of blood containing excessive amounts of non-protein nitrogen, 0.8 mg. or over, per 1 cc., it is rather better to repeat the determination with a smaller quantity of the filtrate.

Because of the large number of non-protein nitrogen determinations recorded in various papers from this laboratory during the last few years, it has seemed to us worth while to make a series of parallel determinations by our old process¹ and by the method described in this paper. These are given on the following page.

NITROGEN DETERMINATIONS BY DIRECT NESSLERIZATION.

III. AMMONIA IN URINE.

By OTTO FOLIN AND W. DENIS.

(From the Biochemical Laboratories of the Harvard Medical School and of the Massachusetts General Hospital, Boston.)

(Received for publication, July 27, 1916.)

Having succeeded in finding a thoroughly practical way of Nesslerizing micro Kjeldahl digestion mixtures without a preliminary isolation of the ammonia, it seemed abundantly worth while to try to eliminate the use of the air current in the determination of the ammonia in urine. To us this was an old problem, and we were by no means hopeful of being able to solve it. The seemingly almost unsurmountable obstacle in the way of determining the ammonia of urine by direct Nesslerization is the strong reducing effect of urine on alkaline solutions of mercuric salts. The most active reducing substance in urine for mercuric salts is creatinine. In the presence of an excess of creatinine the mercury of Nessler's reagent is speedily reduced to the metallic state. With the small amounts of creatinine present in 1 to 3 cc. of urine, turbid unworkable suspensions of mercurous oxide are obtained. The reducing action and the combination of Nessler's reagent with ammonia take place at substantially the same degree of alkalinity. The highly colored oxydimercuric ammonium iodide is itself reduced by creatinine in such alkaline solution, and when the alkalinity is reduced, as by the addition of sodic bicarbonate, the colored ammonium compound is decomposed. It therefore appears to be impossible to adjust the conditions so as to secure a selective formation of the oxydimercuric ammonium iodide in the presence of notable quantities of creatinine.

While the amounts of creatinine normally encountered in urine prevent the direct Nesslerization of the ammonia, we found

that traces, even large traces, of creatinine have no such effect. In fact pure solutions of ammonia and creatinine in equal concentration can be Nesslerized as if no creatinine were present. The turbidity ultimately produced by the reducing action of such small amounts of creatinine is apparently held in abeyance for a very long time (an hour or more) by the colloidal ammonio-mercury compound and thus does not interfere with the colorimetric comparison.

The reducing activity of dextrose is insignificant in comparison with that of creatinine. 1 mg. of ammonia nitrogen can be Nesslerized in the presence of as much as 50 mg. of dextrose. If only some sufficiently simple method for removing the greater part of the urinary creatinine could be found, the direct Nesslerization of the ammonia in the filtrate might therefore become a feasible process. As a preliminary experiment bearing on this point we tried blood charcoal, which removes the uric acid and a considerable part of the creatinine.

According to Macleod blood charcoal removes as much as 70 per cent of the creatinine; and he, as well as Cole, removed the creatinine in this way before testing normal urines for sugar. We did not think that blood charcoal could be made to meet the needs of our problem, chiefly because we believed that it would absorb the ammonia as well as creatinine.

We soon found, however, that by suitable treatment of urine with blood charcoal (Merck's, which is free from ammonia) all the ammonia of the urine goes into the filtrate, while the uric acid, the phenols, and more than 90 per cent of the creatinine are taken out by the charcoal. The reducing substances are removed so effectively by this treatment that the Nesslerized filtrates remain perfectly clear for several hours.

For the colorimetric determination of ammonia in urine by direct Nesslerization we have arrived at the following method: To 10 cc. of urine in a large test-tube or small flask add 1 cc. 25 per cent *m*-phosphoric acid, 9 cc. distilled water, and 2 gm. Merck's blood charcoal. Shake well for at least 1 minute and filter through a dry filter paper. Transfer 1 to 5 cc. of the filtrate to a 100 cc. volumetric flask, add distilled water to a volume of about 70 cc., and Nesslerize by the addition of 15 cc. of the same Nessler's solution which we use for total nitrogen determinations.

Make up to volume with distilled water, mix, and compare in the usual manner with the color obtained by Nesslerizing 1 mg. of ammonia nitrogen in another 100 cc. flask.

The *m*-phosphoric acid is added partly as an acid; *i.e.*, so as to be sure to have the ammonia as salts, for free ammonia is in part absorbed by blood charcoal. The reason why the *m*-phosphoric acid rather than some more common acid is used is that the charcoal does not remove albuminous materials, and we have found that the *m*-phosphoric acid is necessary in the case of albuminous urines, and also in the case of many normal specimens.

Instead of adding 1 cc. 25 per cent *m*-phosphoric and 9 cc water, it will often prove more practical to add 10 cc. of a previously diluted *m*-phosphoric acid solution; but the fact that dilute solutions of this acid do not keep well should not be forgotten.

On the basis of the parallel determinations recorded below we are inclined to believe that this new, simple method gives absolutely reliable results for the ammonia of urine.

NITROGEN DETERMINATIONS BY DIRECT NESSLERIZATION.

IV. UREA IN URINE.

BY OTTO FOLIN AND W. DENIS.

(From the Biochemical Laboratories of the Harvard Medical School and of the Massachusetts General Hospital, Boston.)

(Received for publication, July 27, 1916.)

All methods for the determination of urea in urine dependent on purely chemical processes for the hydrolysis of the urea are apparently destined to become antiquated, if not forgotten, because of the abundant supply of urease now available for such hydrolysis. It would be easy to devise an excellent direct Nesslerization method for the determination of urea in urine on the basis of the Folin-Pettibone process, in which the urea is decomposed by the help of phosphoric acid and heat; but, recognizing the superiority of urease for the hydrolysis of urea we decided first to see whether a combination of direct Nesslerization with a urease decomposition of the urea could be obtained.

The starting point of our research was the idea that *m*-phosphoric acid, which we had found so effective for the removal of blood proteins, might be used to remove from urine the urease materials added for the hydrolysis of the urea, and should thus yield filtrates suitable for direct Nesslerization. The outcome proved to be quite in accordance with our expectations and the remainder of the research has consequently been only a matter of deciding certain minor details in the practical application of the method to urine. Concerning these details there is much room for choice and individual preference.

Since the added urease-containing material is removed before Nesslerization of the ammonia, it makes no difference within rather wide limits whether much or little of the material is used, or whether the ferment is added in the form of a concentrated enzyme powder. or as crude soy bean flour suspension.

502 Nitrogen Determinations by Nesslerization. IV

In our work we use chiefly "soja bean meal" sold as a food for diabetics, and which can be obtained from any wholesale drug house.

The urea determination is made as follows: Transfer 1 cc. of undiluted urine by means of an accurate Ostwald pipette to a 100 cc. volumetric flask. Add 0.1 to 0.25 gm. soy bean meal in the form of a 1 per cent suspension. Stopper the flask and let stand for 1 hour at room temperature, or for 15 minutes in a water bath at about 50°C. Add 25 cc. water and 1 cc. fresh *m*-phosphoric acid solution (25 per cent) and mix; then add about 1 gm. Merck's blood charcoal and a little more water (25 cc.). Shake, make up to volume, mix, and filter through a dry filter paper.

The soy bean meal suspension is made as follows: Transfer 5 gm. soy bean meal to a mortar, add 15 cc. water, and rub until a uniform paste is obtained. Add more water and mix. Rinse the mixture into a flask or bottle with water, using in all about 400 cc. water. Add 100 cc. alcohol making the total volume of the suspension about 500 cc. 10 to 15 cc. of the freshly shaken suspension is used for each determination. The suspension remains good for at least 2 days at ordinary room temperature.

We have verified the findings of Mateer and Marshall that the jack bean is much richer in urease than the soy bean; the latter product has, however, the great advantage, at present, that it is readily available in finely powdered form and is not at all expensive.

Transfer from 5 to 20 cc. of the filtrate to a 100 cc. measuring flask. The amount taken should contain 0.7 to 1.3 mg. ammonia nitrogen. Dilute with distilled water to 60 to 70 cc. Nesslerize in the usual way and compare with the standard (1 mg. ammonia nitrogen Nesslerized in another 100 cc. flask).

Urea determinations in urine are seldom made except in connection with total nitrogen determinations, and for the latter determination the urine is first diluted from five to twenty times. Instead of decomposing 1 cc. of undiluted urine for the urea determination, 10 cc. of this diluted urine may, of course, be used.

The following parallel urea (+ ammonia) determinations made by the colorimetric micro method and by the Marshall-Van Slyke method show that the results obtained are identical. We

have not considered it worth while to check off the results by any other method, because all who have worked with urease are agreed that it decomposes urea quantitatively and does not decompose any other nitrogenous constituent of urine.

NITROGEN DETERMINATIONS BY DIRECT NESSLERIZATION.

V. UREA IN BLOOD.

By OTTO FOLIN AND W. DENIS.

(From the Biochemical Laboratories of the Harvard Medical School and of the Massachusetts General Hospital, Boston.)

(Received for publication, July 27, 1916.)

The determination of urea in blood is nearly identical with the method for the determination of urea in urine described in the preceding paper. The essential points in the method are (a) the decomposition of the urea with urease, (b) the precipitation of the proteins and added urease material with *m*-phosphoric acid, and (c) direct Nesslerization of the protein-free filtrate.

To 5 cc. fresh oxalated blood in a 50 cc. volumetric flask add about 0.1 gm. soy bean meal in the form of a 1 per cent suspension. Stopper, and let stand for 1 hour. Then add 25 cc. water and 2 cc. fresh *m*-phosphoric acid solution (25 per cent), and make up to volume. Mix thoroughly, let stand for at least 45 minutes (or over night if convenient), and filter. To the filtrate add 0.5 gm. Merck's blood charcoal, shake well, and filter. In the case of normal or approximately normal blood, transfer 10 cc. of the last filtrate (corresponding to 1 cc. of the original blood) to a 25 cc. volumetric flask, add 5 cc. of Nessler's reagent (made according to our formula), make up to volume, mix, and compare at once (within 10 minutes) in the colorimeter against 0.25 mg. ammonia nitrogen Nesslerized in a 50 cc. flask (with 10 cc. Nessler's reagent).

If only 2 cc. of blood is available for the urea determination the process is exactly the same (including the coagulation in a 50 cc. flask) except that 20 cc. of the final filtrate, corresponding to 0.8 cc. of blood, is taken for the Nesslerization.

As in the non-protein nitrogen determination, it is often desirable to have two or three different ammonia nitrogen standards

506 Nitrogen Determinations by Nesslerization. V

ready for the color comparison. This is especially the case when working with only 2 cc. of blood, or when working with blood in which abnormally high urea contents may be expected.

In the parallel urea determinations recorded below we used (a) the colorimetric method described above, and (b) Marshall's urease method, in which the ammonia was isolated by aeration and titrated. The urease used in connection with the second method was a concentrated product prepared by the Arlington Chemical Company according to Van Slyke's directions.

THE RELATIVE EXCRETION OF PHENOLS BY THE KIDNEYS AND BY THE INTESTINE.

BY OTTO FOLIN AND W. DENIS.

(From the Biochemical Laboratories of the Harvard Medical School and of the Massachusetts General Hospital, Boston.)

(Received for publication, July 27, 1916.)

Last year we described a new colorimetric method for the determination of phenols in urine,¹ and also published a series of analytical results illustrating the total phenol content of urine, and the distribution of the phenol between the free and the conjugated forms. At that time our plan was to extend the research in an analogous manner first to feces and finally to blood, and we hoped to bring these investigations to a conclusion in a reasonably short time. The outcome has not been entirely satisfactory. Our phenol determinations in stools suffer from one theoretically serious source of error which we have not been able to remove. Our "phenols" in feces, include any tyrosine which may be present, and if it were not for the fact that the total phenols (even including the tyrosine) are often extraordinarily small in comparison with the phenol content of urine, we should not care to record our findings or the method by which they were obtained.

Inasmuch as practically no quantitative investigations are available concerning the phenol contents of stools, and since practically nothing is known concerning the quantitative relationship between the total phenol contents of the urine and of the feces, our method and our results are not without value, at least for purposes of general orientation with regard to this subject.

Our method for the determination of the total phenols in feces is as follows: The 24 hour amount of feces is weighed (on a

¹ Folin, O., and Denis, W., *J. Biol. Chem.*, 1915, xxii, 305.

good platform balance), thoroughly mixed,² and a portion weighed out to within 0.1 gm. The quantity of feces to be taken varies greatly with the nature of the stool. In soft, pasty stools 20 gm. is a convenient quantity, in more solid feces 10 gm. can be handled with better results, while in diarrheal stools it is sometimes necessary to use 40 to 50 gm. The stool if semisolid is thoroughly mixed with 40 cc. of water and transferred quantitatively to a 100 cc. volumetric flask; in liquid stools the addition of water is of course unnecessary. 20 cc. of 10 per cent solution of sodium aluminium sulfate (or ordinary alum) is first added, with shaking, and then 1 cc. of 5 per cent lead acetate solution is added. The flask is then filled to the mark with water, shaken, allowed to stand 5 minutes, and its contents are filtered through a folded filter. 5 cc. of the filtrate is pipetted into a 100 cc. volumetric flask, to it are added 25 cc. of water, 3 cc. of phosphotungstic phosphomolybdic acid reagent³ and 25 cc. of 20 per cent sodium carbonate solution. The flask is then filled with water to the 100 cc. mark, shaken, and allowed to stand for 15 minutes (or longer if convenient), after which its contents are centrifuged or filtered and read in the Duboscq colorimeter against a standard solution of phenol.

As a standard we use a solution of pure phenol in 0.1 *N* HCl containing 1 mg. of the former substance in 10 cc. 10 cc. of this solution when treated with the same amounts of reagent, and sodium carbonate, as are used with the unknown, and made up with water to 100 cc. gives a convenient standard when the colorimeter is set at 20 mm. As even the highest grades of phenol contain some water, it is always necessary to standardize the standard phenol solution by means of the iodometric titration.⁴

² A shaking machine can be advantageously used at this point to obtain thorough mixing of soft stools; by employing an ordinary steel spatula, with patience, excellent mixtures may, however, be obtained without the use of a shaker.

³ This reagent is prepared by boiling gently for 2 hours 750 cc. water, 100 gm. sodium tungstate, 20 gm. phosphomolybdic acid, 50 cc. phosphoric acid (85 per cent), and 100 cc. hydrochloric acid (concentrated). At the end of the period of heating the mixture is cooled and diluted to a volume of 1 liter. This formula for the preparation of the phenol reagent is better than our original one. It was worked out by Dr. Richard Bell in this laboratory in connection with another investigation.

⁴ For the method used in this standardization see Folin and Denis, *J. Biol. Chem.*, 1915, xxii, 307.

The precipitation method as outlined above has been tested with "artificial feces" (consisting of a mixture of soap, neutral fat, egg albumin, and calcium phosphate) to which had been added known amounts of various pure mono- and diphenols. In every case 99.5 to 100 per cent of the added phenol was recovered.

In using this method on the excreta of hospital patients, it must be borne in mind that many drugs are phenol derivatives, and would, if excreted even in part by way of the intestine, lead to erroneous results. Salicylic acid and aspirine (acetyl salicylic acid) are the most commonly used examples of this class of drugs, and while these bodies are largely excreted by the kidneys, a sufficient quantity passes out by way of the intestine to cause grave errors in the determination of fecal phenols.

While it is, of course, advisable to make the determinations in fresh material, we have found that in the case of feces from normal persons there was no change in the phenol content on 24 hours storage at $-2^{\circ}\text{C}.$, and but slight increase when the stools were kept at this temperature for 48 hours.

A finding not without interest which has been noted during the working out of the above method, is the fact that the phenols in feces exist in a free or unconjugated condition, as shown by the fact that even after long boiling with mineral acids stool extracts give no higher phenol values than before this treatment.

The determination of phenols in the feces of persons fed on coarse vegetables and fruit is extremely unsatisfactory on account of the difficulty of securing representative samples; therefore and for the purpose of furnishing some basis of comparison it seemed desirable to obtain results on a certain number of normal individuals fed on a test diet which might be used in pathological cases. To this end we have made a number of observations on men (surgical convalescents) who were fed on a diet consisting of 300 gm. of bread, 75 gm. of butter, six eggs, and 1,500 cc. of milk. In a few instances this proved too large an amount of food to suit individual tastes and had to be slightly reduced.

The figures recorded in Table I are cited as showing the normal distribution of phenols in the stools and in urine. The individuals represented, though hospital patients, were normal in that they were convalescent surgical (fracture) cases suffering from

no known metabolism disorder, and because they passed their stools without the aid of laxatives or enemata. The last named point is of the greatest consequence in the study of the phenols of feces, because laxatives and enemata almost invariably bring about a very large increase in the products giving the phenol reaction. Experiments illustrating this fact are recorded in Table II.

SUMMARY.

A colorimetric method for the determination of phenols in stools is described. From a study of the urinary and intestinal phenol excretion in normal men, the conclusion is reached that normally, and in the absence of diarrhea, laxatives, or enemata, a very small fraction (from 7 to 20 per cent) of the phenols formed is eliminated by the intestine.

THE EFFECT OF THE ADDITION OF ALKALI TO SEA WATER UPON THE HYDROGEN ION CONCENTRATION.

By A. R. HAAS.

(From the Laboratory of Plant Physiology, Harvard University, Cambridge.)

(Received for publication, July 18, 1916.)

The addition of alkali to sea water has been employed in important biological experiments¹ such as those upon the development of sea urchin eggs, parthenogenesis, spermatozoan activity-duration of life of *Paramæcia*, cell oxidation, rhythmic movements, and permeability.

It has been observed that the NaOH reacts with the magnesium in the sea water in such cases, causing the precipitation of magnesium hydrate. Artificial sea water containing no magnesium has been used in some instances to obviate this difficulty.² Before it is possible in experiments in which NaOH is added to sea water to correlate the results with the decreased hydrogen ion concentration, it is necessary to study first the effect which such additions of alkali have upon the hydrogen ion concentration of the sea water.

Sodium hydroxide solution was prepared by titrating with normal oxalic acid solution, using phenolphthalein as indicator. The strength of the alkali was found in this way to be 2.4813 N. The alkali was purposely made very strong so as to cause as little dilution of the sea water as possible. Care was taken in all operations to protect the alkali from the CO₂ of the atmosphere. Especially the lower outlet of the burette, where ordinarily the drops of alkali become exposed to the CO₂ of the air, was kept continually bathed in an atmosphere of hydrogen.

¹ Höber, R., *Physikalische Chemie der Zelle und der Gewebe*, Leipsic, 4th edition, 1914, 195.

² Harvey, E. N., *Carnegie Institution of Washington, Year Book No. 10*, 1911, 123.

A 24 cc. sample of sea water was then titrated by the use of the gas chain, at a temperature of 21°C. The resulting hydrogen ion concentrations of the sea water were observed for small additions of the alkali. The same figures were obtained a second time when a duplicate titration was made.

Results of Additions of Alkali to Sea Water upon the Hydrogen Ion Concentration.

These gas chain titration values of the hydrogen ion concentration of sea water for small additions of strong alkali have been plotted upon logarithmic paper. The abscissa represents burette readings of the alkali, while the ordinate represents the hydrogen ion concentration. It should be noted that the ordinates do not give P_H numbers except at the heavy cross lines. If, for example, we begin at 14 on the ordinate and read downwards along the ordinate, we read the following hydrogen ion concentrations: 1×10^{-14} heavy line, 1.5×10^{-14} , 2×10^{-14} , 3×10^{-14} , 4×10^{-14} ,

5×10^{-14} heavy line, 6×10^{-14} , 7×10^{-14} , 8×10^{-14} , 9×10^{-14} , 10×10^{-14} , or 1×10^{-13} heavy line, 1.5×10^{-13} , etc.

At any hydrogen ion concentration along the ordinate we can readily obtain the hydroxyl ion concentration by subtracting the hydrogen ion concentration from 1×10^{-14} . If at 1×10^{-8} , we wish to know the hydroxyl ion concentration of the sea water instead of the hydrogen ion concentration, we subtract 1×10^{-8} from 1×10^{-14} which gives us 1×10^{-6} as the hydroxyl ion concentration of sea water when the hydrogen ion concentration is 1×10^{-8} .

The titration curve shows that on adding alkali to sea water the hydroxyl ion concentration at first rises rapidly and then very slowly until the magnesium hydrate has all been precipitated. After this, further additions of alkali cause a more rapid rise in the concentration of the hydroxyl ion but this rise is soon checked by the precipitation of calcium hydroxide. After the calcium hydroxide is all precipitated further addition of alkali will cause a corresponding increase in the concentration of the hydroxyl ion.

Burette readings of the 2.4813 N NaOH added to 24 cc. sea water.

FIG. 1. Curve showing changes in the hydrogen ion concentration of sea water upon the addition of alkali at 21°C.

TRANSLOCATION OF SEED PROTEIN RESERVES IN THE GROWING CORN SEEDLING.

By C. J. V. PETTIBONE AND CORNELIA KENNEDY.

(From the Biochemical Laboratory, Department of Physiology of the Medical School, University of Minnesota, Minneapolis.)

(Received for publication, July 24, 1916.)

Among the important biochemical problems which have reached solution in the last decade few have attracted more interest than the controversy over the form in which the digestion products of the proteins are transported by the blood to the various tissues of the animal body. Folin and Denis¹ demonstrated an increase of non-protein nitrogen, which was neither urea nor ammonia, in the blood of cats after injection of glycocholic acid into an isolated loop of the intestine. Abderhalden² succeeded in isolating various amino-acids from large quantities of blood, but concluded that the amounts present represented surplus amino-acids which were left over after the circulating protein had been built up in the intestinal wall. Van Slyke and Meyer³ by their now well known method for the estimation of amino nitrogen demonstrated not only the presence of amino-acids in the blood, but a marked increase in their amount after a protein meal. Abel, Rowntree, and Turner⁴ have isolated amino-acids from the blood by vividiffusion. As the supporters of the theory that amino-acids were resynthesized to protein in the intestinal wall before entering the circulation had based their conclusions upon negative evidence—the failure to demonstrate the presence of amino-acids in the blood—the results above cited served to settle the controversy.

In view of the establishment of the fact that in animals the proteins of the food enter the blood stream and are transported to the tissues at least in large measure in the form of amino-acids, it would be of interest to settle the same problem in connection with the transference of reserve seed proteins in plants. A study was undertaken of the form in which the reserve proteins of

the kernel are transported in the growing corn seedling. The demonstration that the translocation of protein nourishment is by way of the amino-acids would be of interest in establishing another link in the fundamental resemblances of the plant and animal kingdoms.

That amino-acids are present in plant tissues and fluids has been shown by various investigators, and many specific amino-acids have been detected by characteristic color tests, or even have been isolated. But there appears to have been no attempt to correlate the presence of amino-acids with a transference of protein food reserves, although such a possibility has been suggested by Thompson in his work on the Alaska pea.⁵

In approaching the problem one is confronted with the difficulty that the seed undoubtedly does not produce large quantities of amino-acids and then transfer them to the growing parts of the plant where resynthesis of protein is taking place. The hydrolysis of the seed protein may well be considered a gradual process, the hydrolytic products being transported to the growing parts and built up into tissue protein. Thus it will be seen that in any part of the seedling the total amounts of amino-acids present at any one time will be small, even though the transference of protein in this way is considerable. Thus to establish the point it will be necessary to demonstrate the presence of amino-acids in the flowing sap. If the protein material of the seed diminishes, and that of the growing parts increases while amino-acids are constantly present in both places, the presence of these compounds in the flowing sap will indicate beyond question that the protein transference is made by way of the intermediate stage of the amino-acids.

Our observations were made on corn seedlings grown in flat granite or porcelain dishes of tap water, the kernels being supported on wire gauze or perforated porcelain plates so that they were kept moist, but were not completely submerged. The water was changed frequently. For the estimation of total nitrogen and amino-nitrogen in the various parts of the plant twenty seedlings of the size desired were selected, the plumule and rootlet removed, and the parts dried *in vacuo* at 70-80°.

⁵Thompson, T. G., *J. Am. Chem. Soc.*, 1915, xxxvii, 230.

Total nitrogen was determined by the Kjeldahl method. For amino nitrogen the material was ground, and extracted with hot water, acidified with acetic acid, and the determination of amino nitrogen carried out according to the micro method of Van Slyke.³ It will be seen from the accompanying tables and graphs (Table I and Graph 1) that as the total nitrogen of the seed diminishes the combined total nitrogen of root and plumule increases, indicating transference of nitrogenous material. The sum total of

nitrogen in the entire seedling shows an average value approximating that in the unsprouted kernel, with perhaps a tendency toward slight increase, due no doubt to assimilation of nitrogen or nitrogen compounds from the air or water.

The figures and graphs for amino-acid nitrogen (Table II, Graph 2), on the contrary, show fairly uniform values, excepting the rather considerable increase in the amount in the seed during the early stages of growth up to the time where the plumule had reached $\frac{1}{2}$ inch in length. It is evident that amino-acids are present in seed, rootlet, and plumule at all stages of growth up to the 10 inch plumule, and in fairly uniform amounts. Thus nitrogenous material is transported, and amino-acids are present

at all stages of growth in each portion of the seedling. It only remains to demonstrate that the transported nitrogen is in the form of amino-acids.

To do this it was necessary to demonstrate the presence of amino-acids in the flowing sap. The process proved to be extremely laborious, as the amounts of sap to be obtained from corn seedlings are extremely small, and since the concentration of amino-acids in the sap would naturally be low, fairly large amounts of sap would be required for each analysis. The sap was obtained as follows.

Seedlings were grown as described above. When the plumules had grown to a length of about 4 inches, they were cut off about 1 inch above the seed with a sharp scalpel. In order that the sap which slowly collected on the top of the stump might not evaporate, the dish, containing usually 300 to 500 seedlings, was covered with an inverted Petri dish resting upon a moistened towel laid around the edge of the dish. This formed a moist chamber which prevented the evaporation of the exuding sap and also kept the cut ends of the plumule stump from drying. From ten to fifteen such dishes were prepared at a time, making a total of from 3,000 to 5,000 seedlings.

It was found that tiny drops of sap gathered on the plumule stump in the course of about 3 hours. These drops were removed by means of a capillary pipette, and the sap was collected in a test-tube. This test-tube was kept in a freezing mixture, so that the sap was frozen as soon as collected, thus preventing spoiling. The seedlings usually survived the amputation, and after bleeding sap 24 to 36 hours, began to grow. A second cutting was sometimes attempted, but with indifferent results, as the seedlings usually turned brown and died during the 1st day. Sap from such seedlings was rejected. In this way it was possible to gather in the neighborhood of 10 cc. of sap in a day, the time and care of the growing seedlings making it possible to obtain 15 to 20 cc. per week.

The sap was analyzed as follows. 10 cc. of sap were made up to 100 cc. with ethyl alcohol, and allowed to stand over night. A faint cloudiness indicated the presence of traces of protein material. The alcoholic filtrate was concentrated to 2 to 3 cc. *in vacuo*, 30 cc. of water were added, and the concentration was

repeated. The liquid (about 1 cc.) was carefully rinsed into the burette of the Van Slyke apparatus and a determination of the amino-acid nitrogen made. In this way eleven portions of about 10 cc. each were collected and analyzed. In all cases the analysis showed amino-acid nitrogen. It seemed apparent, therefore, that amino-acids were present in the flowing sap. There remained the possibility, however, that the compounds present were peptides or simpler protein decomposition products.

To settle this question the last six portions of sap in alcohol were mixed two and two, each solution thus representing about 20 cc. of sap. Equal portions of each combined filtrate were then analyzed for amino-acids, one as described above, the other after removal of the alcohol and heating in a water bath with concentrated hydrochloric acid for 24 hours (Van Slyke⁶). In case the amino compounds present in the sap were peptides or simpler proteoses, the amino determination after hydrolysis would show a marked increase in the amount of amino nitrogen, due to the setting free of amino-acids formerly held in peptide linkage. The ratio of amino-acid nitrogen in the unhydrolyzed sap to the amount after hydrolysis would vary according to the complexity of the peptides present and according to their relative amount. By consulting the figures in Table III, 26 A and B, 27 A and B, and 33 A and B, it will be seen that in two out of the three sets of

⁶ Van Slyke, D. D., *J. Biol. Chem.*, 1912, xii, 295.

duplicates there actually was an increase in amino nitrogen after hydrolysis. Apparently then, the sap contained, in addition to free amino-acids, also some more complex products of protein hydrolysis, but, as the value was in no case doubled, the amount appears to be small in comparison to the amount of free amino-acids.

CONCLUSION.

Thus it is clear that amino-acids are present in the flowing sap of corn seedlings. Since these compounds are present at all times in seed, rootlet, and plumule, their presence in the flowing sap coupled with the above demonstrated migration of nitrogen, indicates beyond question that the process of transportation of the reserve proteins of the seed, to furnish building material for the proteins of the growing parts, takes place in a manner analogous to the transportation of protein food supplies in the animal organism. The appearance of a slight cloudiness when the sap was mixed with alcohol, and the relatively slight increase in amino-acid nitrogen after hydrolysis suggest, however, that a portion of the nitrogen may be transported in the form of soluble protein or protein hydrolytic products of peptide type. It is the intention of one of us to investigate this point further.

THE INFLUENCE OF THE COLOR FROM THE SODIUM PICRATE IN THE DETERMINATION OF CREATININE IN BLOOD AND URINE.

BY F. H. MCCRUDDEN AND C. S. SARGENT.

(From the Laboratories of the Robert B. Brigham Hospital, Boston.)

(Received for publication, July 26, 1916.)

The color obtained on mixing together picric acid and alkali is very similar to that obtained on mixing together picric acid, creatinine, and alkali according to Folin's method of determining creatinine. It seemed reasonable to suppose, therefore, that in a mixture containing much picrate and little creatinine, such as is obtained in determining creatinine in the blood, an undue proportion of the color might be due to the picrate alone and that this color effect might invalidate the final results and so explain certain irregularities we had been finding in carrying out triplicate determinations of the creatinine in the blood.

The experiments recorded here, therefore, were carried out to determine how much the color from the picrate alone affects the results obtained in the determination of creatinine in the blood and urine by the methods of Folin.¹

Analyses 1 to 12 show the extent of inaccuracy in the final result produced by the "picrate" color when the technique for the determination of creatinine in the blood is employed.² Varying amounts of a 0.005 per cent creatinine in picric acid solution

¹ Folin, O., On the determination of creatinine and creatine in urine, *J. Biol. Chem.*, 1914, xvii, 469; On the determination of creatinine and creatine in blood, milk, and tissues, *ibid.*, 1914, xvii, 475.

² In carrying out the analyses recorded in this paper calibrated pipettes, burettes, volumetric flasks, and a calibrated Duboscq colorimeter were used throughout in the measurements, and the most scrupulous care was taken to use them accurately. In using Ostwald pipettes, for example, numerous weighings show that with our technique the pipettes can give nearly as accurate results as an analytical balance. The time element in making the tests was controlled with a watch.

(0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.1, 1.2, 1.3, 1.4, and 1.5 cc.) were made up to 10 cc. with saturated picric acid solution;³ 0.5 cc. of 10 per cent sodium hydroxide was added and the mixtures were allowed to stand 10 minutes. The mixture containing 1.0 cc. of creatinine solution was used as the standard and set at 20 in the Duboscq colorimeter. Table I and Chart A show the results.

TABLE I.*

A Comparison of Actual Readings with Calculated Readings when Creatinine Is Determined According to the Technique for Creatinine Determination in Blood.

Experiment No.	Amount of creatinine solution.	Calculated reading.	Actual reading.
1	0.0	∞	25.7
2	0.5	40	25.7
3	0.6	33.3	22.0
4	0.7	28.6	25.5
5	0.8	25.0	21.7
6	0.9	22.2	23.4
7	1.0	20.0	20.0
8	1.1	18.2	21.2
9	1.2	16.7	18.7
10	1.3	15.4	20.4
11	1.4	14.3	18.0
12	1.5	13.3	18.4

* All determinations were made in duplicate.

The results indicate clearly that the influence of the picrate color is very great; note especially Experiment 1 showing that the "picrate" color alone is nearly as strong as that of the standard.

Experiments 13 to 23 were designed to determine how much deviation from the calculated readings the "picrate" color causes when creatinine is determined according to the technique for the determination of creatinine in the urine.

To a series of saturated solutions of picric acid (20 cc. each) were added respectively 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.1, 1.2, 1.3, 1.4, and 1.5 cc. of a 0.001 per cent solution of creatinine in 0.1 N hydrochloric acid; 1.50 cc. of 10 per cent sodium hydroxide were added, the solution was allowed to stand 10 minutes and then made up to 100 cc. The mixture containing 1.0 cc. of the crea-

³ 1.2 gm. of picric acid in 100 cc. of water.

CHART A. A comparison of actual readings with calculated readings when creatinine is determined according to the technique for creatinine determination in the blood. The abscissæ indicate the number of cc. of 0.005 per cent creatinine used; the ordinates indicate readings in the colorimeter. The full line shows calculated readings; the dotted line actual readings.

tinine solution was used as a standard and set at 20.0 in the colorimeter. Table II and Chart B show the results.

It will be seen from the chart and table that in the technique for urine analysis, especially when the amount of creatinine is large, the effect of the "picrate" color is not very great.

A possible answer to the question of why the "picrate" color effect is comparatively great in the case of the determination of creatinine in the blood, comparatively small in the case of the determination of the creatinine in the urine, was discernible in the fact that the proportion of picrate to creatinine is about ten times greater in the concentrations of these substances used in the

TABLE II

A Comparison of Actual Readings with Calculated Readings when Creatinine Is Determined According to the Technique for Creatinine in Urine.

Experiment No	Amount of creatinine solution	Calculated reading	Actual reading
13	0 5	40 0	30 9
14	0 6	33 3	28 6
15	0 7	28 6	25 5
16	0 8	25 0	24 4
17	0 9	22 2	21 9
18	1 0	20 0	20 0
19	1 1	18 2	18 4
20	1 2	16 7	16 4
21	1 3	15 4	15 6
22	1 4	14 3	14 4
23	1 5	13 3	13 3

standards for blood analysis than in those used for urine analysis. For example, in the 10 cc. mixture of picrate and creatinine used as the "blood creatinine" standard in the foregoing tests there are 0.120 gm. picric acid and 0.00005 gm. creatinine—a proportion of 2,400 picrate to 1 creatinine; in the 100 cc. mixture of picrate and creatinine used for the "urine creatinine" standard, there are 0.240 gm. picric acid and 0.001 gm. creatinine—a proportion of 240 picrate to 1 creatinine. It is inevitable, therefore, that the color due to picric acid should have a greater disturbing effect on the final result in the blood analysis than it has in the urine analysis.

CHART B. A comparison of actual readings with calculated readings when creatinine is determined according to the technique for creatinine determination in the urine. The abscissæ indicate the number of cc. of 0.001 per cent solution of creatinine used; the ordinates indicate readings in the colorimeter. The full line shows calculated readings; the dotted line actual readings.

To determine more precisely how great a disturbance the presence of picric acid itself has on the reaction it became necessary to determine the color effect of the picrate in terms of the creatinine color. Since the creatinine color cannot be developed except in an excess of picrate itself, it is not possible to compare the "picrate" color alone with the "creatinine" color alone. But it is possible to determine what concentration of creatinine in picrate gives a color twice as intense as that given by the picrate alone. In such a mixture half the color is due to the picrate and half to the creatinine; and the amounts of creatinine and picrate present are, therefore, those which give equal amounts of color.

A set of tests according to the blood analysis technique showed that a solution containing 0.12 gm. of picric acid and 0.00025 gm. of creatinine in 10 cc. gives approximately twice as deep a color as a solution containing 0.12 gm. picrate alone in 10 cc. A set of tests by the urine analysis technique showed that a solution containing 0.24 gm. of picrate and 0.0005 gm. creatinine in 100 cc. gives approximately twice as deep a color as a solution containing 0.24 gm. picrate alone. From these tests it is clear that 0.00025 gm. creatinine gives as deep a color as 0.12 gm. of picrate, or 0.0005 gm. of creatinine gives as deep a color as 0.24 gm. of picrate. In other words creatinine gives $\frac{0.12}{0.00025}$ or $\frac{0.24}{0.0005}$; that is, 500 times as deep a color, gram for gram as picrate.⁴

We now have the data to determine how much of the color in the creatinine determination is due to picrate alone and how much to creatinine.

In the blood analysis the amount of picrate present in the 10 cc. is 0.12 gm., the amount of creatinine in an average standard 0.00005 gm. If now we call the unit of color that degree of color given by 1 mg. of picrate alone, then, in the blood analysis, 120 units of color are due to the picrate and $500 \times 0.05 = 25$ units due to the creatinine. In other words five-sixths of the color is due to the picrate alone and only one-sixth to the creatinine.

In the urine analysis the amount of picrate present in 100 cc.

⁴This ratio of 500 to 1 is only a rough approximation.

is 0.24 gm., the amount of creatinine in an average standard 0.001 gm. Using the same unit of color as before—that given by 1 mg. of picrate alone—240 units of color are due to picrate alone and 500 units of color to creatinine. In this case about two-thirds of the color is due to creatinine and only one-third to the picrate alone.

SUMMARY.

The data show that the color due to the creatinine in the determination of creatinine in the urine is only two-thirds of the total color; and indicate clearly how important it is, therefore, to use amounts of urine having very nearly the same amounts of creatinine as the standard. The data emphasize further a fact that we have long recognized empirically and acted upon in our own laboratory; namely, that, in determining creatinine from day to day in any one patient as a control of the care with which 24 hour specimens of urine are collected, the amount of creatinine in the specimens taken for analysis should be the same from day to day; in other words the urine should be made up to the same volume from day to day and the same aliquot portion taken for analysis.

From the data it is clear that in the determination of creatinine in the blood the color due to creatinine is such a small proportion of the total color that *analysis gives no information whatever concerning the amount of creatinine present*; the slight variations obtained in duplicates can be accounted for by slight variations in the amount of picric acid in the solution.

In the light of these experiments it is clear that all that has been written hitherto concerning the physiology of creatinine and creatine needs careful revision; much of it will have to be modified, some of it—all that concerning creatinine and creatine in the blood, for example—will have to be rejected altogether.

THE RELATION OF AMIDE NITROGEN TO THE NITROGEN METABOLISM OF THE PEA PLANT.*

BY BARNETT SURE AND W. E. TOTTINGHAM.

(From the Department of Agricultural Chemistry, University of Wisconsin, Madison.)

(Received for publication, July 11, 1916.)

INTRODUCTION.

In studies of nitrogen metabolism in plants, one of the most striking observations has been that asparagine accumulates to a considerable extent in shoots of growing seedlings, especially when germinated in the dark for 2 to 3 weeks, but disappears during later growth. This observation has been the subject of much discussion in physiology for a number of years. Different theories have been proposed to explain the physiological rôle of asparagine and the chemical processes involved in its accumulation in plant metabolism, but the problem has not yet been definitely solved.

The first significant study of asparagine in plants was made by Robert Sachsse as early as 1873.¹ His method included extraction of the tissue with water, precipitation of proteins by mercuric chloride, removal of mercury by hydrogen sulfide, treatment of the concentrated residue by alkaline potassium hypobromite, and volumetric measurement of the nitrogen evolved. This gave the ammoniacal nitrogen. The amide nitrogen was determined by the increase of nitrogen obtained by the method following acid hydrolysis. It is sufficient to state that this method is open to several sources of error.

Schulze,² in 1880, in working with lupine seedlings, reported that about 30 per cent of the total nitrogen was in the form of asparagine. He used two methods: the crystallization method, which consisted in extracting the

* Abstract of a thesis presented by Barnett Sure in partial fulfilment of the requirements for the degree of B.S. at the University of Wisconsin.

¹ Sachsse, R., *Über eine Methode zur quantitativen Bestimmung des Asparagins*, *Landw. Versuchs.*, 1873, xvi, 61.

dried seedlings and evaporating to a small volume, when the substance crystallized out; and the Sachsse acid hydrolysis method. He explains the rôle of asparagine in the metabolism of the plant as due to destruction of nitrogen-free substances in excess of the protein catabolism; hence the accumulation of protein decomposition products, of which asparagine is one.

Müller,² in 1887, in working with dahlia, tobacco, coleus, corn, and various other plants, also found a great accumulation of this amide, but offers a different explanation for its formation. He believes that asparagine is formed synthetically and not as a decomposition product. It is possible, he states, that sugars are oxidized to alcohols and acids, and by the union of the acids with ammonia asparagine might be formed. This would explain the disappearance of nitrogen-free substances as carbohydrates, and at the same time the accumulation of asparagine.

Schulze then modified his theory to assume that amino-acids resulting from proteolysis might be converted into asparagine.

Suzuki,⁴ of the Agricultural Experiment Station of Tokyo, proved that ammonia, when offered in the form of ammonium salts to the plant in water cultures in larger doses than are needed for the immediate protein formation, is transformed into asparagine and is stored up as such for further use.

Prianischnikow and Schulow⁵ conducted experiments similar to that of Suzuki, and also found that by supplying ammonium salts an increased yield of asparagine was obtained. They suggest that asparagine might result from the union of ammonia and aspartic acid with loss of water, but that aspartic acid may not be the particular substance on which ammonia acts.

Wassiliew⁶ has corroborated Schulze's findings that the disappearance of asparagine at maturity is accompanied by an increase in protein material, but the most significant fact which he brings out is that the production of amide nitrogen is accompanied by a decrease in amino-acid nitrogen.

Suzuki,⁷ in later experiments, grew one lot of plants in the presence and another in the absence of oxygen. In the absence of oxygen he found no increase of asparagine over the control plants, but a striking increase was found in the presence of oxygen. He also found a remarkable decrease of amino-acids in the presence of oxygen. He therefore concludes that asparagine originates from the oxidation of amino-acids.

The purpose of the present investigation was to determine whether, during germination, there is a direct relation between the disappearance of amino-acids and the accumulation of amides, as determined by methods more strictly quantitative than those formerly used.

EXPERIMENTAL.

In order to show clearly any relation between amino-acids and amides during early stages of plant growth, it appeared important to follow the changes of total and water-soluble nitrogen, as well as various components of the latter.

Analytical Methods.—The method used for the determination of the ammoniacal and amide nitrogen was that introduced by Folin⁸ for urine analysis, employing aeration before and after acid hydrolysis. The method used for the determination of amino-acid nitrogen was that introduced by Van Slyke.⁹ Van Slyke's improved method determines only the α -nitrogen of amino-acids by allowing reaction for 5 minutes, the other nitrogen of the diamino and heterocyclic amino-acids not being involved. The present investigation, therefore, resolves chiefly into a study of the relation of α -amino-acids to the accumulation of amides in the metabolism of the plant.

Preliminary separation trials gave quantitative results from a mixture of pure asparagine, glycocoll, and ammonium sulfate. It was observed that, when only 1 mg. of amino nitrogen from asparagine is measured in the Van Slyke amino apparatus, asparagine reacts with only one of its nitrogen atoms with nitrous acid in 5 minutes, probably with the α -amino nitrogen atom. However, when 5 mg. of amino nitrogen from asparagine are measured in the apparatus, asparagine reacts with only 95 per cent of the amino nitrogen. In working with plant materials, therefore, corrections were made accordingly.

In all cases where ammonia was present it was removed before subjecting the plant extract to determinations of amino nitrogen.

The pea plant (Little Gem, dwarf variety) was chosen as the

⁸ Folin, O., Approximately Complete Analysis of Thirty "Normal" Urines, *Am. J. Physiol.*, 1905, xiii, 45.

object of investigation because its seed has a large amount of reserve material and the seedling will grow for almost a month in pure sand before decomposition effects become prevalent. Since it was the purpose of this investigation to compare seedlings at several stages of germination, the pea was consequently a desirable plant to work with. Moreover, it is a member of the legume family, in which protein metabolism is especially extensive.

About 400 gm. of air-dried peas were soaked for about 12 hours in distilled water and planted in sand in a greenhouse. The sand was spread about 8 inches deep on soil under a bench and watered with distilled water daily. By suspending gunny sacks around the bench the seedlings were partially etiolated. This was for the purpose of stimulating the accumulation of amides by retarding photosynthesis. After 5 days the seedlings were harvested and freed from sand by washing quickly in a rapid stream of water. Care was taken to avoid loss of epidermis from the cotyledons. By thus exposing the seedlings to water for a very short time no appreciable loss of nitrogen by leaching could have occurred.

Approximately 100 gm. of green material were used for preparing extracts; 10 gm. were weighed out in duplicate for moisture determinations; and duplicate portions of about 10 gm. were taken for total nitrogen determinations. Duplicate extracts were prepared by grinding weighed amounts of green tissue with sand in a mortar. Care was taken to add a 2 per cent solution of phenol after triturating each portion of samples using 10 cc. per 500 cc. of extract. 5 cc. of toluene were also added per 500 cc. of the same extract. The crushed tissue was treated with water, extracting to a volume of about 450 cc., then heated to boiling, and six to seven drops of a 10 per cent solution of acetic acid were added to coagulate the proteins. The coagulum was filtered off on quantitative filter paper, washed well with boiling water, and the filtrate diluted to 500 cc. Portions of 25 cc. were taken, in duplicate, for total water-soluble, ammoniacal, and amide nitrogen determinations.

A second crop was harvested after 13 days of growth, another after 19 days, and the last after 26 days. The methods of analysis were the same throughout the different stages of growth.

It was thought possible that by soaking the peas over night

before planting some nitrogen might have been extracted. Duplicate samples of air-dried peas were therefore soaked and the extract was analyzed for total nitrogen. Only 0.07 per cent of the total nitrogen of the seeds was found in the extract, showing that, as far as this investigation is concerned, the amount so lost is practically negligible.

Appearance of the Plants at the Different Stages of Germination.

The seedlings were at all stages healthy and vigorous, with the exception of the cotyledons at the last stage. At the 26th day stage the shoots were healthy, but the cotyledons gave evidence of bacterial decomposition in some cases. Hence, although care was taken to reject decaying material, no great emphasis can be placed on the analytical data procured from the cotyledons at that stage.

After 5 days the seedlings were about 5 to 6 cm. tall, after 13 days a pair of leaves appeared, after 19 days three to four pairs of leaves were present, and after 26 days the growth rate was apparently declining, due to exhaustion of the reserve food. Etio-lation was not complete, as indicated by the pale green color of the seedlings.

After 5 days of growth the plants were too small for separation of shoots and cotyledons. Separation of these two different parts of the plant was not made, therefore, until the later stages.

All data are consolidated in Tables I to III, and are presented in the graphs of Figs. 1 to 3.

DISCUSSION.

Total Nitrogen.

Shoot.—The total nitrogen in the shoot percentagely at 26 days is a little more than double that found in the original seed. This is what might be expected according to Schulze's theory that decomposition of carbohydrates in the shoot is more rapid than that of the protein bodies. Nitrogenous substances, therefore, increase percentagely, although the *absolute* amounts ought to remain unchanged if no nitrogen is being lost by exudation.

One might regard it possible that the total nitrogen involved has not been dealt with in this investigation, due to exudation of soluble nitrogen compounds from the seedlings to the soil. There is conflicting evidence on this point in the literature and no definite conclusion can be made. However, the opportunities for such loss of nitrogen were the same in this work as those which obtain in field conditions of practical agriculture.

The fact that the total nitrogen increases in shoots of growing seedlings percentagely is also brought out by Thompson¹⁰ in his work on pea seedlings.

Cotyledon.—The total nitrogen in the cotyledon decreases, presumably, due to the fact that, during germination, the cotyledon is the seat of protein catabolism. A great portion of the nitrogenous substances are transported to the shoot; hence the decrease of the nitrogen percentagely in the cotyledon.

Total Water-Soluble Nitrogen.

Shoot.—The total water-soluble nitrogen represents the total nitrogen obtained from determinations made on aliquots of the water extract. It includes the water-soluble protein nitrogen.

It will be noted from the graphs of Fig. 1 that the curve for the total water-soluble nitrogen is nearly parallel with the curve for the total nitrogen. Table II shows that this form of nitrogen is continually increasing as percentage of the total nitrogen with the exception of the last stage, where a slight decrease takes place.

Cotyledon.—The graphs of Fig. 1 indicate that the total water-

¹⁰Thompson, T. G., The Total Amino Nitrogen Content in Seedlings of the Alaska Pea, *J. Am. Chem. Soc.*, 1915, xxxvii, 230.

soluble nitrogen in the cotyledon varies nearly parallel with the total nitrogen; and Table II shows that, in the cotyledon, the total water-soluble as per cent of the total nitrogen also increases throughout the full period investigated, with the exception of the last stage, where a slight decrease occurs.

Insoluble Nitrogen.

Shoot.—The insoluble nitrogen constitutes the difference between the total and water-soluble nitrogen.

It will be noted from Table II that the insoluble nitrogen, as per cent of the total nitrogen, is continually decreasing with the exception of the last stage, where it has increased.

Cotyledon.—The insoluble nitrogen in the cotyledon, as per cent of the total, is also decreasing throughout all the stages of metabolism with the exception of the last stage, where it has increased. From what has been previously mentioned regarding the decay of the cotyledons at this stage, it would appear that this late increase of insoluble nitrogen might be ascribed to the action of bacteria, as well as to synthesis of insoluble from water-soluble compounds.

Water-Soluble Protein Nitrogen.

Shoot.—It will be noted from the graphs of Fig. 2 that the water-soluble protein nitrogen, in the shoot, decreases throughout the different stages of growth as per cent of the total water-soluble nitrogen. Until the 13th day of growth this decrease might be ascribed largely to the fact that other water-soluble nitrogenous bodies, as ammonia and especially amides and α -amino-acids, begin to accumulate. From the 13th to the 26th day it would be due partly to the utilization of water-soluble proteins for the accumulation of insoluble compounds, as shown in Fig. 1.

Cotyledon.—The same relation which obtained in the shoot applies to the cotyledon, with the exception that at the last stage the water-soluble protein nitrogen has somewhat increased as per cent of the total water-soluble nitrogen.

Ammoniacal Nitrogen.

Shoot.—Only traces of ammonia are present in the seed, but this constituent accumulates apparently as a by-product of pro-

tein metabolism. Its amount after 5 days of growth as per cent of the total water-soluble nitrogen is almost constant at 5, 13, and 19 days in the shoot, but decreases considerably at 26 days. It is of interest to note that while the ammonia is decreasing the amide nitrogen is rapidly increasing in the shoot.

Cotyledon.—In the cotyledon there is a considerable accumulation of ammonia at 19 days to the extent of 15 per cent of the total water-soluble nitrogen. It decreases, however, to 6 per cent at 26 days, which is slightly less than the percentage at 5 and 13 days.

It seems possible, since both ammonia and carbohydrate material disappear when amides accumulate that, as Müller originally proposed, amides might be produced synthetically from these two classes of substances.

Amide Nitrogen.

Shoot.—The amide nitrogen is continually increasing in the shoot during all the stages of growth. At the last stage it forms 28 per cent of the total water-soluble nitrogen or 17 per cent of the total nitrogen. While amides accumulate in the largest proportions with respect to the total water-soluble nitrogenous constituents, the results obtained are not as high as previous investigators have reported. This may be due to faulty methods of analysis formerly used.

It will be noted that at the last two stages of growth as the amides accumulate the α -amino-acids and ammonia decrease.

Cotyledon.—After 13 days' growth the amides almost completely disappear from the cotyledons. This would indicate that at that stage the small amounts of amide produced in the cotyledon after 5 days' growth have been transported to the shoot. Amides accumulate in the greatest proportions at 19 days in the cotyledon. It is interesting to note that the α -amino-acids drop from 25 per cent of the total water-soluble nitrogen at 13 days to none at 19 days in the cotyledon, when the amides have accumulated to a greater extent than in the shoot.

Amino Nitrogen.

Shoot.—The α -amino nitrogen in the shoot, while it increases in the first two stages of germination as a result of protein hydroly-

sis, decreases both in the third and fourth stages when the amide nitrogen is rapidly increasing.

Thompson,¹⁰ applying the Van Slyke method to the Alaska pea, after 14 days of growth, found the amount of amino nitrogen to be 19.41 per cent of the total in the leaves and stem. The result reported here is 12.0 per cent, after 13 days of growth. This investigator does not give specific information about his method; i.e., whether he removed ammonia and proteins and corrected for amide nitrogen reacting from his plant extract. If he omitted any of the foregoing steps, his results would be high. One must consider, moreover, that he worked with a different variety of pea plant grown under non-etiolating conditions.

Cotyledon.—The relation between α -amino-acids and amides in the metabolism of the etiolated pea plant is very well brought out in the cotyledon. The α -amino-acids drop from 25 per cent of the total water-soluble nitrogen at 13 days to none at 19 days while the amides accumulate from practically none to 28 per cent of the total water-soluble nitrogen.

Rest Nitrogen.

Shoot and Cotyledon.—The rest nitrogen constitutes the water-soluble nitrogen unaccounted for by our methods of analysis. It is obtained by subtracting the sum of the water-soluble protein, ammoniacal, amide, and amino nitrogen from the total water-soluble nitrogen. It would include the nitrogen other than the α form of diamino-acids, heterocyclic amino-acids, peptones, and polypeptides, and other nitrogenous compounds.

In the later stages of germination these bodies accumulate to over one-half of the total water-soluble nitrogen. Lack of knowledge regarding the specific compounds of this fraction of the total nitrogen indicates the limitations of even the present technique. In the near future we should have reliable methods for determining these bodies with a view to learning what physiological rôle they play in the metabolism of the plant.

SUMMARY.

The main observations made in this study of the nitrogen metabolism of the etiolated pea plant may be summarized as follows.

1. After 26 days the total nitrogen more than doubled percentage in the shoot. This was possible only when carbohydrate decomposition was more rapid than protein disintegration, and indicates that during the early stages of growth of the etiolated pea plant, the shoot is the seat of rapid carbohydrate catabolism.

2. The total nitrogen somewhat decreased in the cotyledon and, during earlier stages of growth, α -amino-acids accumulated in the cotyledon even to a greater extent than in the shoot. This indicates that catabolism is the predominant type of change in protein material of the cotyledon during germination.

3. The water-soluble nitrogen maintained a rather constant proportion of the total nitrogen throughout the period of growth investigated with the exception of the first stage, when it accumulated to a considerable extent.

4. Ammonia was present only in traces in the seed, but accumulated as germination advanced. It fluctuated in the cotyledon somewhat parallel to amide nitrogen, but in the shoot it decreased while amide nitrogen increased.

5. Amides accumulated in the shoot throughout all the different stages of germination, but not in so large proportions as previous investigators have reported. This may be due to the faulty methods of analysis formerly employed. In the cotyledon the amide nitrogen fluctuated somewhat at early stages, but later increased remarkably, while α -amino-acids were disappearing rapidly.

6. Amides accumulated while carbohydrates and ammonia decreased. It may be inferred that they were produced synthetically from the latter compounds. The evidence for such a view from this study, however, is insufficient to be conclusive.

7. α -Amino-acids accumulated rapidly, especially in the cotyledon during the earlier stages of growth. In the later stages of growth they decreased considerably in the shoot and disappeared rapidly and completely from the cotyledon.

8. The accumulation of amides simultaneously with the decrease of α -amino-acids and ammonia in the shoot indicates that α -amino-acids serve for amide production in the nitrogen metabolism of the etiolated pea plant.

- Sodium hydroxide, rate of solution of casein by, influence on, of ethyl alcohol and glycerol, 129
- picrate, influence of color of, in determination of creatinine in blood and urine, 527
- Starch, ingested, in phlorhizin diabetes, 327
- Sugar acids, epimeric monocarboxylic, relation between configuration and rotation of, 355
- of blood in phlorhizin diabetes, influence on, of ingested carbohydrate, protein, and fat, 93

Sugar acids of blood, and renal permeability, effect of surgical procedures on, 25

Sulfur metabolism, 61

— and nitrogen, relative eliminations of, in the dog in inanition and subsequent feeding, 61

Sulfuric acid, conjugated, of funis mucin (mucoitin sulfuric acid), 373

— and urochloralic acids, ethereal, synthesis, in the organism, effects of temperature and fever on, 301

SURE, B., and TOTTINGHAM, W. E. The relation of amide nitrogen to the nitrogen metabolism of the pea plant, 535

THYMINE-4-aldehyde, synthesis of, 99

TOTTINGHAM, W. E. See SURE and TOTTINGHAM, 535

Translocation of seed protein reserves in the growing corn seedling, 519

Trypsin, dialysis of, and the proteolytic action of protein cleavage products, 121

UREA in blood, 505

— in urine, 501

Uric acid, accumulation in tissues during suppression of urine, 319

— acid solvent power of normal urine, 205

Urine, ammonia in, 497

Urine, aromatic constituents of, 337, 401, 409

— and blood, determination of creatinine in, influence of color of sodium picrate on, 527

— of cow, non-phenolic volatile oils of, 387

— of goat, non-phenolic volatile oils of, 401

— of horse, non-phenolic volatile oils of, 409

—, human, non-phenolic volatile oils of, 409

—, nitrogen in, 473

—, normal, uric acid solvent power of, 205

—, suppression, accumulation of uric acid in tissues during, 319

—, urea in, 501

Urochloralic and sulfuric acids, ethereal, synthesis, in the organism, effects of temperature and fever on, 301
